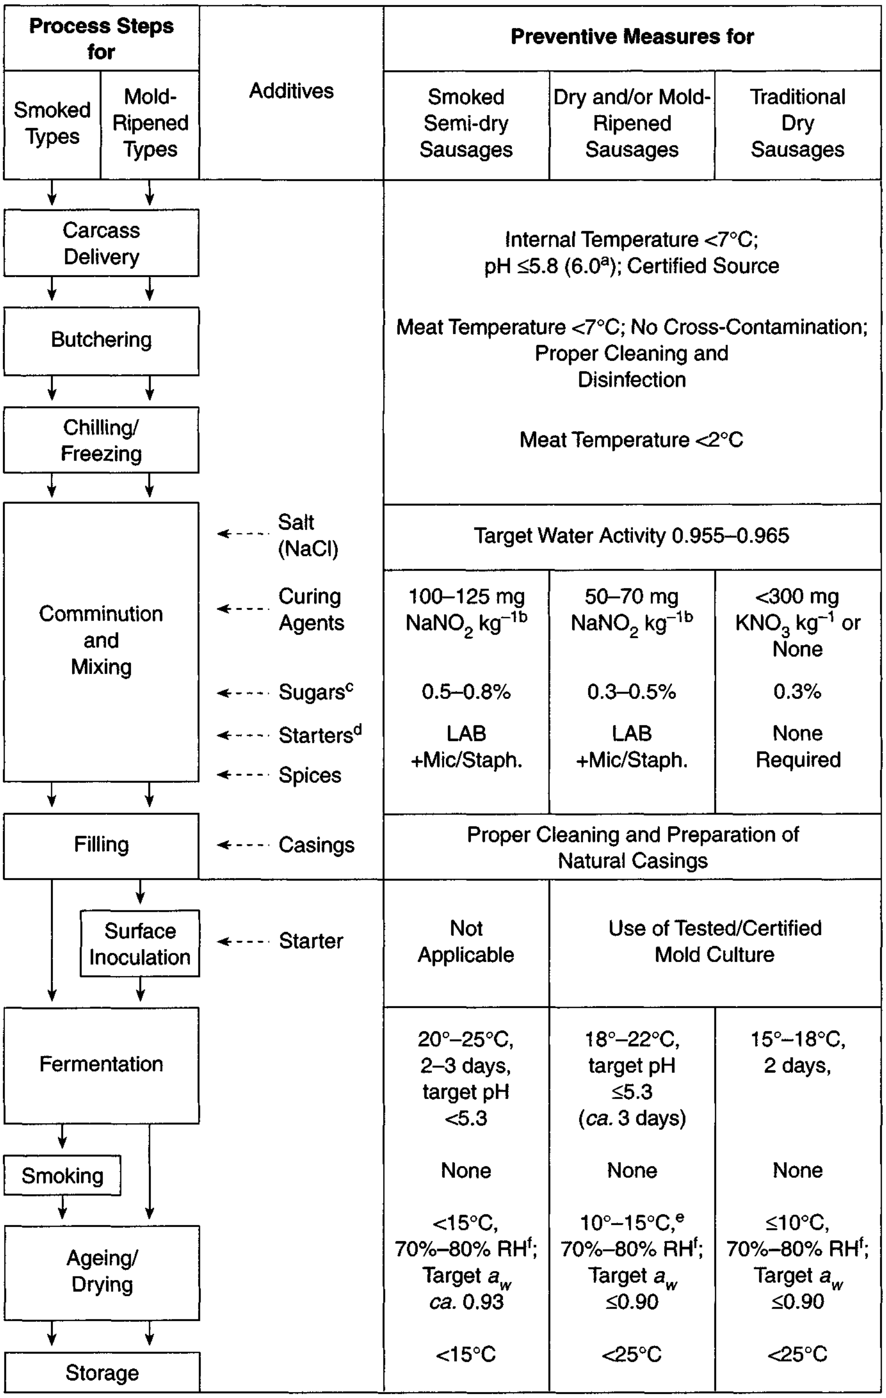
A delay in acid formation not only increases the risk of growth of pathogens but also leads to elevated numbers of Enterobacteriaceae causing off-odors and off-flavors. Improperly cleaned natural casings may contaminate the surface of the sausages with Enterobacteriaceae and inhibit drying of the product, thus favoring growth of these bacteria. The most frequent cause of spoilage of fermented sausages is undesired metabolic activities of lactobacilli. Use of excessive amounts of fermentable sugars, in conjunction with insufficient drying and elevated ageing and/or storage temperature, results in high levels of lactic and acetic acids, sometimes even in hole formation and swollen packs due to CO_2 production by heterofermentative lactobacilli.[72]

Lactobacilli are also involved in the formation of gray or greenish discolorations of sausages; this is related to hydrogen peroxide formation. Peroxides attack heme compounds and polyunsaturated fatty acids and thus lead to color and flavor defects, particularly if soft, improperly stored fatty tissue has been used.[72] Individual species and strains differ widely in their ability to accumulate and to destroy hydrogen peroxide.[30,114] Strong producers are often found among strains of *L. sakei* and *L. curvatus* because these species, unlike *L. plantarum,* possess flavin-dependent oxidases.[87] However, many strains of lactic acid bacteria from meats contain catalase activity when grown on myoglobin- or heme-containing media,[135] or heme-independent "pseudocatalase" (Table 19-2).[50] Thus, net hydrogen peroxide production in meat may be low even in the absence of catalase-positive acid-sensitive microorganisms. Nevertheless, practical experience indicates that oxygen



Process Steps for		Additives	Preventive Measures for		
Smoked Types	Mold-Ripened Types		Smoked Semi-dry Sausages	Dry and/or Mold-Ripened Sausages	Traditional Dry Sausages

[a] In exceptional cases; adjustment of sugar addition and fermentation conditions may be necessary.

[b] With max. 500 mg Na-ascorbate/kg.

[c] Rapidly fermentable by the starter used. 0.8% should be used if meat pH is significantly above 5.8.

[d] LAB, lactic acid bacteria; Mic/Staph., *Micrococcus/Staphylococcus*. Starters must be active at the fermentation temperature selected.

[e] For mold-ripened products, temperature should be lowered to about 10°C after 2 days of fermentation.[153]

[f] RH, relative humidity. Adjustment depending on pH and a_w of sausage (see text).

Figure 19-2 Preventive Measures To Control Growth of *Salmonella enteritica*, *Staphylococcus aureus*, and *Listeria monocytogenes* during the Manufacture of Fermented Semi-dry and Dry Sausages. *Source:* Reprinted from F.K. Lücke, Fermented Sausages, in *Microbiology of Fermented Foods*, 2nd ed., Vol. 2, B.J.B. Wood, ed., pp. 441–483, © 1998, Aspen Publishers, Inc.

should be excluded from raw sausage mixtures as far as possible, and enough peroxide-destroying activity should be present during fermentation. This is achieved, for instance, by slowing down the rate of acid formation by lowering the fermentation temperature, and/or by the addition of appropriate starters (ie, lactic acid bacteria that do not accumulate peroxides, with suitable catalase-producing microorganisms such as *Micrococcus* and *Staphylococcus* strains).

After fermentation, undesired mold growth and/or oxidative changes in the lipid fraction (rancidity) limit the shelf life of most semi-dry or dry sausages.

19.8 RECENT AND FUTURE DEVELOPMENTS

In 1988–89, the present author collected the opinions of various experts from industry and research on desirable improvements of sausage fermentation.[113] Priority was given to shortening ageing times (ie, obtaining better flavor in less time) and prolonging shelf life by inhibiting rancidity, while acceleration of acid production ranked low. However, in the last few years, suppression of pathogens (in particular enterohemorrhagic *E. coli*) and amine formation have become major issues. In addition, there is continuous interest in making microbiological and chemical changes during sausage ripening more predictable, a prerequisite for standardization and automation of the manufacture of these products.

19.8.1 Novel Cultures

Possible developments in the field of starter cultures have been discussed in various reviews,[68,69,83,113] and requirements for good starters are given in Section 19.5. It must be emphasized that starter cultures are just one factor affecting quality and safety of fermented sausage and cannot make up for incorrect formulations, eg, use of rancid fat, addition of too much sugar, or incorrect ripening conditions. One difficulty is that, unlike milk and malt, meat cannot be pasteurized before inoculation without drastically changing its properties. This means that any starter culture for sausage ripening must be able to compete with the indigenous microflora of the sausage mixture. Moreover, selection and improvement of starters for better aroma in less time and long shelf life is difficult because the chemical and biochemical reactions affecting sensory properties are very complex and insufficiently understood. This limits the possibility of screening a large number of strains in model systems, as well as the prospects of tailoring strains by means of genetic engineering. However, novel starters may increase product safety, and much work has been devoted to the selection of strains antagonistic to pathogens. Bacteriocins formed *in situ* by lactic starter cultures may contribute to the inactivation of *Listeria monocytogenes* (see Section 19.6.1), and *Penicillium nalgiovense*[59] and meat lactobacilli[20] have been engineered to lyse *Staphylococcus aureus* by means of lysostaphin. However, prospects of using such strains are limited. For example, bacteriocins from lactic acid bacteria are insufficiently stable in meat systems, have little if any effect on Gram-negative bacteria, and bacteriocin-resistant variants of target bacteria may arise.[111] Moreover, *Staphylococcus aureus* can be controlled well by the use of existing technology, making it difficult to explain to the public and to regulatory bodies the necessity of using genetically engineered organisms. For further discussion of bacteriocins and their use see Chapter 12.

The complexity of reactions leading to optimal aroma and flavor of fermented meats makes it very difficult to accelerate sausage ripening. However, selected enzymes may have an effect on sausage ripening. For example, Næs et al.[127] obtained a more intense flavor of a fermented sausage by adding a peptidase isolated from *Lactobacillus paracasei.*

19.8.2 Novel Methods of Fermentation Control

A mass of data on the behavior of pathogens is now available in electronic form,[155] and predictions may also be made on the performance of lactic acid bacteria in sausages as affected by water activity, temperature, and other parameters.[98,145] Mathematical models for sausage fermentation have been published,[41,188] and a model to predict inactivation of *Enterobacteriaceae* during sausage ripening has also been published.[11] Such tools may be helpful in optimizing existing, and developing new, processes.

On-line sensors for various fermentation parameters (temperature, pH, relative humidity, air velocity, equilibrium humidity of the product) are available,[154] and data may be used to control the fermentation.[179] This could lead to shorter ripening time and less labor caused by manually adjusting the ripening climate or transporting the products from one chamber to another. For example, a product pH below 5.3 means that the fermentation is nearly finished, and the temperature and relative humidity in the ripening chamber should be lowered.

19.8.3 Novel Products

While there is a large variety of fermented milk products, fermentation has not been employed to any extent in the manufacture of meat products other than "classical" fermented sausages. However, as shown for bacon,[182] it may be possible to improve the safety of nonfermented meats by addition of selected lactic acid bacteria.[4,60] To date, such attempts have limited success because of sensory differences (sour taste is not tolerated in most meat products) and shortening of shelf life. Moreover, the decrease in water-binding capacity connected with lowering the pH to 5.3 is undesirable in most pasteurized meats except those that are subsequently dried, eg, "Kochsalami."[151] A better knowledge of the role of microorganisms in aroma and flavor formation may be applied to develop raw ham and nonfermented meat products with improved sensory properties. Fermentative production of aroma concentrates to be added to such meats may be an option.

20 Fresh and Further-Processed Poultry

Geoffrey C. Mead

CHAPTER CONTENTS

20.1 Introduction
20.2 Sources of product contamination with human pathogens and spoilage organisms
  20.2.1 The large-scale, live-bird production system
  20.2.2 Biological control measures in poultry production
20.3 The processing plant
  20.3.1 Outline of processing
  20.3.2 Microbiological problems in processing
  20.3.3 Microbial attachment to carcasses
  20.3.4 Effects of processing on carcass contamination
  20.3.5 Development of hygienic processing machinery
  20.3.6 Application of the Hazard Analysis Critical Control Point (HACCP) system
  20.3.7 Decontamination of processed carcasses
20.4 Raw poultry products
  20.4.1 Possible hazards from psychrotrophic pathogens
  20.4.2 Uneviscerated carcasses
20.5 Further-processed products
20.6 Concluding remarks
References

20.1 INTRODUCTION

The term *poultry* normally includes chicken, turkey, duck, goose, and guinea fowl, although it is sometimes used to encompass species such as pigeon, ostrich, pheasant, and other game birds. Over the last 40 years, the poultry meat industry has undergone considerable expansion, and poultry now accounts for some 27% of the world's meat consumption. Chicken and turkey are the principal types of poultry meat, with chicken comprising two-thirds of the total production and an annual output of more than 33,000 million birds worldwide.[2] Production methods vary from that of the free-range village chicken of developing countries to the highly intensive systems used in the more developed world, where poultry production is one of the most technologically advanced sectors of agriculture. In many of the larger companies around the world, the operation is partly or completely integrated, and a single organization may own breeding farms, hatcheries, feed mills, growing units, and primary and further-processing plants. Over the years, there have been continuous improvements in bird growth performance and feed conversion, and considerable economies of scale in both production and processing. The latter now involves a high degree of automation and, overall, the industry is particularly efficient and progressive.

Poultry meat is perceived as cheap, wholesome, and nutritious, being high in protein and low in fat, with a favorable content of unsaturated fatty acids. Unlike pork and beef, there are no religious constraints on consumption. Also, poultry meat is easy to prepare in the home and widely utilized in fast-food establishments. In developed countries, the boom in poultry consumption has been fueled by the recent expansion in further processing, which leads to better utilization of the meat and upgrading of off-cuts or poorer cuts. It also provides portion control, convenience, variety, and relatively consistent product quality. Thus, poultry meat is now used to prepare many of the traditional products that previously were made only from red meats, as well as a variety of other items. These include cut portions, reformed roasts, rolls, escallops, grillsteaks, burgers, turkey hams, nuggets, sausages, frankfurters, salamis, bolognas, and ready meals. Both product appearance and flavor can be varied as required. With cured products, however, the degree of curing and smoking is less than that used in red meat processing, and the goal is to provide distinctive flavors rather than preservation. Product formulations vary widely in different countries and are influenced by local tastes and customs. The details are usually confidential to particular companies.

There are two main kinds of poultry muscle: white (breast) and red (leg). These have structural and physiological differences, as well as different *postmortem* pH values. Breast muscle has a pH value in the range 5.6–5.8, and leg muscle is pH 6.1–6.4. Both types of muscle are relatively susceptible to microbial spoilage when stored in the unfrozen state. The shelf life of raw meat depends upon the combined effects of certain intrinsic and extrinsic factors, including the numbers and types of psychrotrophic microorganisms present initially, the storage temperature, muscle pH and type, as well as the kind of packaging material used and gaseous environment of the product during storage.

Despite the healthy image among consumers, raw poultry is a common vehicle of foodborne human disease, especially from *Salmonella* and *Campylobacter*. Illnesses from each of these agents have an estimated annual incidence in the United States (US) alone of up to 4 million cases.[18] The organisms are carried asymptomatically in the intestines of a varying proportion of all healthy birds, and they frequently become contaminants of processed carcasses. Other foodborne pathogens that are often present on carcasses include *Clostridium perfringens*, a common intestinal organism, and *Staphylococcus aureus*, which is carried on the skin and in the nasopharynx of some birds and may also be acquired from the colonization of processing equipment.[76] Generally, both of these organisms occur in only low numbers, and the meat is unlikely to become hazardous unless it is temperature abused and extensive multiplication occurs. Chicken and turkey are the main types of poultry incriminated in human food poisoning, but their respective involvement[18] does not reflect the consumption figures, which are always lower for turkey. Unlike chicken, turkey is often cooked as a whole carcass, particularly for receptions and other large gatherings and on festive occasions. Large carcasses may be cooked a day in advance of consumption and, due to their size, they take a relatively long time to thaw, cook, cool, and reheat.[18,123]

Although *Salmonella* is recognized as the most important foodborne pathogen associated with poultry meat, the extent to which poultry is responsible for human salmonellosis is presently unknown, because most cases are sporadic and cannot be traced to source. Data from outbreaks in the United Kingdom (UK), however, suggest that 20% to 35% of reported cases could be associated with poultry consumption.[119] During the period 1989–1991, 11% of 392 general outbreaks of salmonellosis were linked to poultry meat and *S. enteritidis* was incriminated in 48% of these.[129] Throughout much of the world, the recent rise in human salmonellosis has been paralleled by an increase in the incidence of *S. enteritidis* in poultry flocks. There is also concern about the possible presence of *S. typhimurium* DT104, which is particularly pathogenic for humans and shows multiple resistance to antibiotics, including some of those used in human medicine. In a study of human illness from this organism, chicken from butchers' shops, restaurants, and food take-away establishments was among the risk factors identified.[145] *Salmonella* contamination of poultry carcasses varies widely between countries.[141] Table 20-1 shows the results of a number of surveys published between 1990 and 1994, with an incidence of positive samples between 4% and 100%. It has been reported[118] that giblets (heart, liver, gizzard, neck) are more frequently contaminated with salmonellas than the carcasses themselves. From 1987 onward, the most common serotype isolated in the UK was *S. enteritidis* PT4, which was responsible for much of the increase in human salmonellosis over the period in question.[119] These results contrast sharply with the situation in Sweden, where salmonellas have been virtually eliminated from poultry meat through a combination of governmental controls and voluntary measures taken by producers. However, the cost of such a program has been considerable and was estimated to be five times that of the British system.[109] Also, Sweden has a much smaller, less complex poultry industry and a colder climate, all of which may contribute to the very low incidence of salmonella-contaminated poultry meat. Other Scandinavian countries with a low incidence are Finland and Norway.

Enteric disease in man from *Campylobacter* is mainly due to *C. jejuni* and *C. coli* and, again, the majority of cases are sporadic, with outbreaks being relatively uncommon. Of all the reported outbreaks of foodborne disease in Europe during 1990 and 1991, only 1.1% were due to *Campylobacter*.[37] Data from sporadic cases suggest that handling and preparation of chicken and poultry liver, and the consumption of undercooked chicken are particular risk factors[119]

Table 20-1 Reported Salmonella Contamination in Poultry and Poultry Products[18,119,141]

Year	*Country*	*Type of Product*	*No. of Samples*	*Percent Positive*
1990	India	dressed broilers	50	4
1990	Netherlands	chicken portions, livers	81	54
1991	UK	chicken (hospital kitchen)	214	45
1991	US	post-chill chicken	57	11
1991	US	retail broilers	36	17–50
1991	India	fresh and frozen chicken	?	100
1991	UK	retail chicken	292	48
1992	US	post-chill chickens	158	72
		cut portions	154	77
1992	Germany	fresh poultry	238	51.7
1992	US	post-chill broilers	560	40.8
1993	US	pre-chill broilers	500	21.8
1993	Germany	poultry products	?	12.7
1994	UK	retail frozen chicken	281	41
		retail chilled chicken	281	33

while, in the US, consumption of chicken, Cornish game hen, and, to a lesser extent, turkey meat have been linked to human campylobacteriosis.[29,44] In most countries, poultry meat is frequently contaminated with campylobacters, and up to 100% of processed carcasses may be positive for these organisms. Counts from skin can exceed 10^4 g^{-1}, but levels of contamination are often reduced during processing to about 10 g^{-1} or 10^3 to 10^6 per carcass.[49,83,142] The organisms could be isolated from breasts, wings, thighs, and abdominal cavities, indicating a general distribution over the carcass. Some reports show a lower contamination rate for frozen chickens in comparison with chilled carcasses, but this may be influenced by the method of isolation and whether or not damaged cells were recovered. Studies suggest[124,134] that campylobacters may survive on frozen chicken for at least 3 to 4 months.

Food poisoning from *C. perfringens* is also associated with poultry, especially turkeys consumed during the festive season. Spores of this organism can survive normal cooking regimes.[123] Although campylobacteriosis and illness from *S. aureus* is declining, outbreaks involving poultry and poultry products are well documented. In the case of *S. aureus*, the cooked meat is usually contaminated by an infected food handler.[47] *Listeria monocytogenes* is a common contaminant of raw poultry and about 60% of chicken carcasses may carry the organism in low numbers.[81,111] It can also be found on cooked poultry in some cases, despite stringent measures to prevent contamination. Cooked chicken nuggets and cook-chill chicken have been implicated in sporadic cases of foodborne listeriosis.[60,61] In the US, turkey hot dogs were the vehicle in one instance, and the same strain of *L. monocytogenes* was isolated from the patient, from hot dogs kept in the patient's refrigerator, and from unopened packs of the same brand of product obtained from a local shop.[11] Other psychrotrophic pathogens are also common on raw poultry meat, especially *Aeromonas* spp. and *Yersinia enterocolitica*,[141] although their public health significance in this context is not entirely clear. Both types of bacteria grow readily on poultry meat under chill conditions, but there is little evidence of any hazard from these organisms when raw poultry products are stored normally. The strains of *Y. enterocolitica* are not usually those associated with human yersiniosis.[27] Verocytoxin-producing *Escherichia coli* O157:H7 has been found in poultry in the US, where strains were isolated from 1.5% of 263 retail samples of chicken and turkey.[31]

20.2 SOURCES OF PRODUCT CONTAMINATION WITH HUMAN PATHOGENS AND SPOILAGE ORGANISMS

20.2.1 The Large-Scale, Live-Bird Production System

The possibilities for contamination of carcasses in the processing plant are strongly influenced by the microbiological status of the live bird and this, in turn, is related to husbandry practices and the efficacy of hygiene control measures throughout the production chain. The stages in a typical chicken operation are shown in Figure 20-1. Elite stock are family groups of in-bred lines carrying certain desirable genetic traits, eg, body conformation, meat yield, and disease resistance. Grandparent stock are bred from the best of elite lines to provide parent birds, which produce the chicks that will be reared for meat production. Broilers are immature birds that are slaughtered at about six weeks of age or less, according to weight requirements. In addition, hens at the end of their useful laying life are also sent for slaughter, usually at specialized slaughterhouses. The meat obtained in this case is used mainly in further processing, ie, in cooked products, soups, etc.

Both breeders and broilers are normally kept on litter (wood shavings or straw) in housing where the environmental temperature and ventilation rate can be controlled. Flock size varies with the type of bird, parent flocks comprising 4,000–5,000 birds and broilers 10,000–20,000 birds or more. Stocking densities are up to 20 birds m^{-2}. Free-range systems represent a small sector of the industry in developed countries and have the disadvantage that there is no control of environmental conditions, while the ground area may need to be changed periodically to prevent any build-up of disease. Hygiene control measures are most stringent at the top of the production pyramid and specific precautions are taken to protect elite and grandparent flocks from disease. For example, no visitors are allowed and staff are required to take a shower and don special protective clothing before entering the houses. The eggs from these flocks are hatched in separate, dedicated hatcheries.

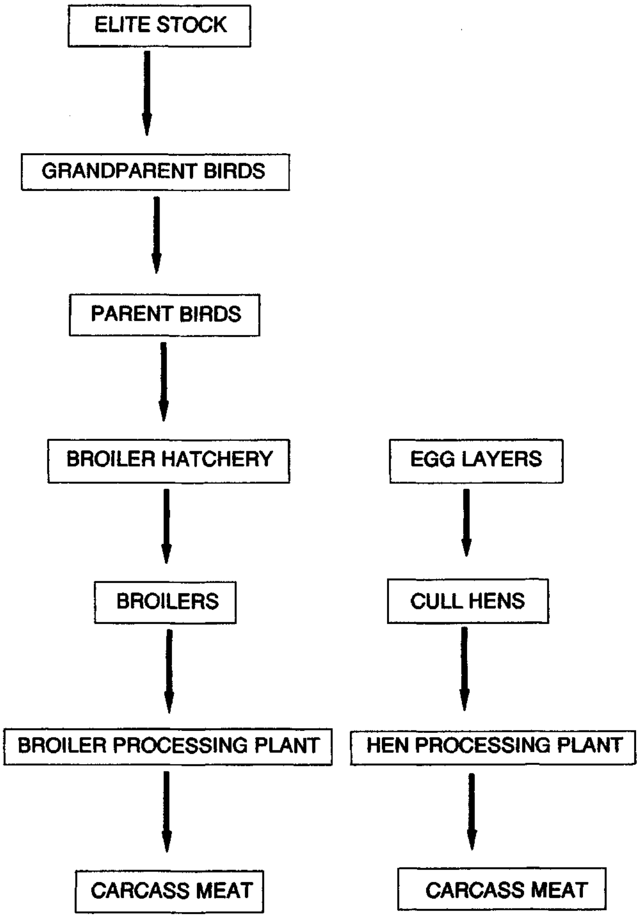

Figure 20-1 Typical Chicken Production Chain.

For all birds, the hatchery represents the area of greatest disease risk and high standards of hygiene are always necessary. The layout of the building should be such that there is adequate separation of "clean" and "dirty" operations and the air flow must pass from clean to dirty areas. Requirements for hygienic operation include easily cleanable surfaces, with no dust traps. Rodents, flies, and other pests must be suitably controlled. Staff are required to wear protective clothing and to exercise good personal hygiene. There should be appropriate facilities for cleaning and disinfecting the egg-collecting vehicles. A regular program of microbiological testing should be used to monitor the efficacy of the cleaning regime throughout the hatchery.

Only visually clean eggs should be incubated and, on arrival at the hatchery, the eggs may be fumigated with formaldehyde. Alternatively, they may be dry cleaned, washed, or dipped in a sanitizing solution. Eggs can be stored for up to seven days before incubation. A further fumigation treatment is often used before the eggs are incubated in "setters," where they remain for 18 days. Then, they should be examined to ensure that embryos are developing and transferred to hatchers for a further three days. Facilities do not normally allow segregation of eggs from different flocks. During incubation, contaminated egg shells and other debris, such as chick fluff, can serve as sources of infection in the incubator and airborne infection can also occur. Once in the egg, salmonellas can multiply rapidly and infect the developing embryo. This will then become a source of infection for other chicks as they hatch. Thus, every attempt must be made to exclude salmonellas from the hatchery environment.

Broiler chickens, or meat birds of other species, may acquire salmonella infections from three main sources: (1) breeding stock via the hatchery, (2) the rearing environment, and (3) contaminated feed. *Salmonella enteritidis* is currently the most common serotype causing human illness in various countries[119] and eggs can be contaminated with this organism, either internally or externally by the time they are laid. Alternatively, eggs may become contaminated after lay by penetration of the shell. *S. enteritidis* is an invasive serotype with an apparent predilection for the reproductive tract of poultry. Infection of the oviduct appears to be a major source of egg contamination[27] thereby causing vertical transmission from parent to progeny. Other invasive serotypes include *S. typhimurium* and *S. virchow*, but the extent to which they are transmitted vertically among poultry flocks is less clear. Most salmonellas are confined to the intestines of infected birds and excreted in the feces. In broiler flocks, both these and the invasive serotypes may spread horizontally from birds that are shedding the organisms to those that are not. Once introduced, infection may be spread via drinking water and feed that rapidly become contaminated in the house. Potential vectors include wild birds, rodents, insects, domestic animals, and humans.

Rodent proofing of poultry houses requires particular attention, while all farm personnel must wear protective clothing and visitors to the farm should be kept to a minimum. Domestic pets should be excluded at all times. From the point of view of hygiene control, all birds should be removed from the house at the end of the rearing period (the "all-in, all-out" principle). In practice, thinning of flocks may occur when birds of certain weights are required before the normal slaughter age. This could result in the introduction of salmonellas and other foodborne pathogens because the houses must be opened up to collect the birds, thus exposing the remaining birds to infection.

When the house is finally emptied, spent litter and feces are usually removed from the farm, after which the equipment and internal environment must be thoroughly cleaned and disinfected. Cleaning of houses is particularly difficult for premises with earthen rather than concrete floors, although they do not always harbor salmonellas. Empty houses should be "rested" before introducing a new crop of birds to allow a natural die-off of any disease agents present. The ideal period is about three weeks, but shorter times become necessary when there is commercial pressure to utilize rearing facilities to the full.

During rearing, the third potential source of salmonella infection is the feed and this is due mainly to the use of contaminated ingredients in which salmonellas may survive processing, or recontamination of feed that occurs at the mill or on the farm. Even one salmonella g^{-1} of feed is sufficient to produce infection.[46] Ingredients of animal origin are known to be prone to salmonella contamination; these include meals from fish, meat and bones, feathers, and blood. In consequence, UK legislation, for example, requires that all processed animal protein, whether home produced or imported, is tested for salmonellas. However, no such requirement applies to vegetable proteins or other ingredients, despite the fact that virtually all ingredients have been shown at various times to be contaminated with salmonellas.[115,152] Nevertheless, measures are taken at feed mills to safeguard the final product, including the application of heat treatment, which is a necessary part of the pelleting process used for broiler feed. The efficacy of the treatment depends upon temperature, time, moisture, and initial levels of contamination, and may involve the use of expander technology or an extrusion process. Recontamination of pelleted feed can occur during air cooling, unless the air being drawn in is filtered. After processing, it is essential that the feed is kept dry because areas of dampness may lead to multiplication of surviving organisms. Water can enter the milling environment via condensation, leaking pipes and roofs, etc. Trucks used to transport feed should be dedicated to this task and be cleaned and disinfected between loads.

The use of ionizing radiation is a possible alternative to heat treatment for poultry feeds, but the high cost is prohibitive. Short-chain fatty acids, such as formic and propionic, are sometimes added to feed and have the advantage of protecting it against recontamination during distribution and storage. The acids have been shown to reduce the incidence of salmonella infection in the birds,[45,54] but appear to have little effect in dry feed. It is only when the feed becomes hydrated after consumption by the birds that significant antibacterial activity is likely to occur. Acid-treated feed should be given throughout the rearing period because the acids have no beneficial effect once the birds have become infected.[45] Many of the salmonellas isolated from feed and feed ingredients are not among the more important causative agents of human salmonellosis. However, there are well-established instances where an association has been evident, eg, the presence of *S. agona* in fish meal in 1970 and subsequent isolation from poultry and human cases of illness. Although it is thought that *S. enteritidis* may have been introduced into poultry flocks via contaminated feed,[115,117] this organism is only rarely isolated from finished feeds or ingredients.

20.2.2 Biological Control Measures in Poultry Production

With the recent increase in human food poisoning from *S. enteritidis*, new approaches to salmonella control have become necessary in the poultry industry. One such approach arises from the recognition that the newly hatched chick is highly susceptible to salmonella infection because it is produced in a strictly sanitized environment, has no contact with parent birds, and is slow to develop an intestinal microflora that could successfully compete with ingested pathogens.[101] Thus, Nurmi and his colleagues in Finland[101,112] developed a simple means of establishing an adult-type gut flora in chicks by dosing the birds orally with suspensions or anaerobic cultures of gut contents from adult, salmonella-free individuals. In this way, the treated chicks became resistant to an oral challenge of about 10^6 salmonellas/bird. The protective effect, which is usually termed "competitive exclusion" (CE), is not significantly influenced by the breed, strain, or sex of bird, but depends upon the introduction of viable bacteria, especially anaerobes.

Although attempts have been made to identify the protective bacteria and develop treatment preparations of known composition, these are generally less protective than anaerobic cultures or suspensions of gut content and, in time, tend to lose their protective capability.[130] Therefore, the most widely used treatment preparations are based on the original approach and are essentially complex, undefined cultures of caecal material. It is necessary, however, to screen them rigorously to ensure the absence of all relevant avian and human pathogens. In practice, CE treatment is used in two ways. The first treatment is for newly hatched chicks that are spray inoculated in the hatchery. The birds are wetted on the upper part of the body and ingest the treatment organisms while preening themselves. The second method is applicable to older birds, usually breeding stock, that are already salmonella carriers and require antibiotic therapy to eliminate the infection. The therapy is followed by administration of a CE preparation via the drinking water to prevent reinfection. The effect of CE treatment on salmonellas entering the gut is largely to prevent their growth, so that the organisms are gradually eliminated. However, the exact mechanism of protection is unclear and is likely to be influenced by factors such as pH and Eh; inhibitory substances such as H_2S, bacteriocins, volatile fatty acids, and deconjugated bile acids; competition for receptor sites and nutrients; and local immunity. For *in vivo* conditions, these factors may be interdependent.

Under laboratory conditions, protection has been demonstrated against at least 10 *Salmonella* serotypes, including both invasive and noninvasive strains, and first becomes evident within a few hours of administering the gut-flora preparation. The degree of protection obtained may be reduced in chicks subjected to stress due to high or low environmental temperatures or feed and water deprivation.[146] On the other hand, most antimicrobial growth promoters and anti-coccidial agents have little or no effect on the protective process. CE treatment has been used routinely in Sweden for a number of years, with no adverse effects on bird health or growth performance.[148] In relation to *Salmonella*, it is seen as an important part of the broiler control program.[149] In trials carried out in other countries, especially The Netherlands, the treatment has reduced both the number of salmonella-positive flocks and the proportion of birds within flocks that become infected (Table 20-2). In the UK, commercial use of CE is mainly confined to breeder chicks at present. Where CE treatment is to be part of the control strategy, salmonella-free chicks are a necessary starting point because the treatment is a prophylactic and cannot be expected to eliminate an existing salmonella infection. The use of CE must also be combined with good husbandry hygiene because, while the protective flora is becoming established, the chicks will remain susceptible to infection. Also, any infected chick is a potent source of infection for its cohorts and, with little microbial competition in its intes-

Table 20-2 Field Trials on Competitive Exclusion (CE) Treatment of Broiler Chicks

tines, will commonly shed 10^7–10^8 salmonellas g^{-1} of feces for other chicks to acquire. Such a large challenge is capable of overcoming the protection offered by CE treatment.

Following the upsurge in poultry infections with *S. enteritidis*, there has been increasing interest in vaccine development because vaccines have been used in the past in controlling the invasive poultry pathogens *S. gallinarium* and *S. pullorum*. Research has centered on live, attenuated, and dead vaccines and some are available commercially. A new inactivated vaccine, which specifically aims to reduce vertical and horizontal transmission of *S. enteritidis*, is being used in the UK. When broiler parent stock are vaccinated with this preparation, it is claimed that chicks show passive immunity for at least 21 days. Although vaccination could have a part to play in controlling specific, invasive salmonellas, there may be little, if any, effect on serotypes that are confined to the alimentary tract, where their reaction with the immune system of the bird is largely unknown. As with CE treatment, successful use of vaccination depends upon other control measures being used simultaneously, especially a high standard of husbandry hygiene.

20.3 THE PROCESSING PLANT

20.3.1 Outline of Processing

In industrial countries, poultry are brought to the processing plant in trucks that are specially designed to hold large numbers of birds in crates or modules that can be readily unloaded. After varying periods of time in the arrival area, the birds are transferred individually to a continuously moving system of shackles, on which they are hung manually by the legs. The birds proceed usually to an electrical stunning machine that either renders them unconscious or actually kills them. This is followed by the bleeding stage, in which the neck is partially severed, either manually or by means of an automatic, rotating knife blade. After bleeding, the birds are scalded by immersion in hot water in order to loosen the feathers. The water temperature varies from 50° to 63°C, depending on the bird species being processed and the ultimate type of product (chilled or frozen). Low scald temperatures are required for birds being sold as chilled products, because this avoids the skin being damaged during defeathering (see below). Feathers are removed from the birds via a series of on-line plucking machines. The machines contain banks of counter-rotating domes or discs with flexible rubber "fingers" mounted on them. These remove the feathers by their scouring action. The next stage is usually to remove the head, which is done by an automatic head puller, and then the feet by means of an automatic foot cutter. Next, the birds are transferred to the evisceration line, where both edible and inedible viscera are removed, either by an entirely manual process in the smaller slaughterhouses, or with the use of automatic machinery. Several different machines are involved, each concerned with a separate operation. Both during and after the evisceration stages, carcasses are spray washed to remove any visible spots of blood or feces and then chilled, either by water immersion or air blast chilling, both of which are continuous processes in the larger premises. In low-throughput establishments, water chilling may be carried out in slush-ice tanks and air chilling in a cold room. Finally, carcasses are weighed, graded, and packaged prior to freezing or chill storage, or they may be transferred to a portioning operation. Although individual processing plants differ in points of detail, the basic process is virtually the same worldwide.

20.3.2 Microbiological Problems in Processing

When birds arrive at the processing plant, they carry a large microbial load and many different kinds of microorganism occur on the skin, among the feathers, and in the alimentary tract.[108,143,144] The process of converting the live bird into an oven-ready product leads to removal of a high proportion of the organisms but, during processing, further contamination can occur at any stage, especially during scalding, plucking, and evisceration, but also from aerosols, processing equipment, and the hands of operatives. Initially, the predominant organisms are Gram-positive rods and micrococci, but the final product has a largely Gram-negative flora, including *Flavobacterium* spp., Enterobacteriaceae, *Pseudomonas* species, and *Actinobacter/Psychrobacter* spp.[5,7,70]

The microbiological problems of poultry processing are similar to those encountered in the slaughter process used for red meat animals, but some features of poultry processing are unique and have possible microbiological consequences. Over the years, for example, the rate of processing has steadily increased and many processing plants are producing 6,000 carcasses or more per hour on a single line. With high-rate processing, the carcasses on the line are very close together and cross-contamination occurs readily. Also, the carcass remains whole throughout the process, which means that the viscera must be removed through a relatively small opening. This operation often leads to gut breakage and contamination of the carcass with gut contents. Furthermore, it is sometimes difficult to clean the abdominal cavity of an entire carcass effectively. Unlike other meat animals, the skin is not removed during processing and is already contaminated with microorganisms when the birds arrive for slaughter.

Conditions during breeding, hatching, and rearing of the birds are conducive to the spread of minority organisms such as *Salmonella*. The problem continues during the transportation of birds to the processing plant, especially when cleaning and disinfection of crates and vehicles is not done properly, so that there is flock-to-flock transmission of foodborne pathogens, even before birds are transferred to the processing line.[14,122] The extent to which cross-contamination occurs subsequently depends upon the conditions of processing, as described below, and the measures taken to control plant hygiene. Because the process is so rapid and the small carcasses cool relatively quickly, there is little opportunity for multiplication of mesophilic bacteria on the carcass itself. However, some microbial growth is possible on certain items of processing equipment and this can lead to increases in carcass contamination. Growth of psychrotrophic bacteria on wet surfaces of equipment occurs more readily and is likely to account for contamination of carcasses with listerias[51,104] as well as spoilage organisms.

20.3.3 Microbial Attachment to Carcasses

Even before the attachment phenomenon was studied in any detail, it was appreciated that the washing of poultry carcasses would normally remove only a fraction of the organisms present on the skin, and even the most efficient post-evisceration spray washer would achieve no more than a 10-fold reduction in count. Also, many organisms located on the skin appear to be largely unaffected by the heating involved in immersion scalding or the use of super-chlorinated process water. An understanding of the mechanism of microbial attachment to carcasses might be expected to facilitate the development of measures to remove and destroy microbial contaminants. The attachment of microorganisms to poultry skin is unlikely to be a simple matter because of the nature of the skin surface and the fact that changes occur as birds pass through different stages of the process. For example, there is a major change in the surface structure as a result of defeathering, which leaves many holes in the skin that can trap bacteria. The skin itself is a complex surface, as shown by electron microscopy, which has revealed an irregular topography with many microscopic channels.[71,135] After chilling, an undefined layer of material has been observed at the surface and this appears to support microbial growth during storage of the carcass.

The initial studies on the attachment of bacteria to chicken skin were based on empirical observations and involved immersing carcasses in buffered saline containing known concentrations of the test organisms.[96,97,98] Only those cells that remained on the skin after washing for 3 minutes were regarded as "attached." It was found that the attachment of *Escherichia coli* increased with time of immersion and was directly related to the number of cells present. Conditions of pH and temperature influenced the rate of attachment. While attached organisms were not easy to remove, those present in the film of liquid over the skin surface could be washed away by the washing technique. It is generally recognized that organisms present in the liquid film are likely to become attached to the skin in the course of time.[66,98,135] The early studies suggested that the possession of flagella was essential for an organism to become attached to poultry skin. Little or no attachment occurred with nonmotile organisms such as a *Klebsiella* spp. or *Lactobacillus brevis*. However, later work[69] showed that nonmotile bacteria comprise >70% of the microflora of processed chicken carcasses, thus casting doubt on the suggestion that flagella are necessarily involved in bacterial attachment. Subsequently, no difference was found between flagellated and nonflagellated bacteria in attachment capability and attachment was unaffected by the presence of fimbriae.[65,66]

The electron microscopical work[71,135] shed new light on the problem and showed that, when the skin was wetted, swelling occurred, as water was absorbed. The swelling appeared to trap bacteria that were already located in crevices and channels in the skin and increased their inaccessibility. Skin swelling is not, however, the whole story. When skin was inoculated without significant wetting, bacterial attachment still occured.[66] Clearly, the situation is complex, and there is likely to be more than one mechanism by which microorganisms become attached to the skin or entrapped in it. Removal of attached bacteria is not easy to achieve in the context of poultry processing. One approach involved the use of 4% D-mannose,[28] which prevented attachment by *Pseudomonas aeruginosa* and also removed attached cells, but this would be too costly for commercial application. Washing in saline helped to remove many attached cells,[136] while use of a surfactant may also be beneficial by changing the surface tension of the water film.[66] Use of trisodium phosphate as a chemical rinse at the end of processing is said to act partly by removing a microscopical layer of surface fat from the skin, which allows attached bacteria to be washed away.[23]

20.3.4 Effects of Processing on Carcass Contamination

It is important that birds are starved prior to slaughter so that the intestines are not distended, thereby reducing the risk of gut breakage during evisceration. The exact period of feed withdrawal is a matter for debate. While at least 3 to 4 hours is necessary for this purpose,[42] there is also support for periods of 9 to 10 hours to ensure that the crop is completely emptied. The disadvantage of extending the withdrawal period is that the feces become more fluid and therefore the chances of cross-contamination during transportation would appear to increase. In any case, transporting birds from the farm to the processing plant tends to increase levels of contamination on the outsides of the birds. Over a 5-hour period, a 10-fold increase in *E. coli* has been observed.[108] During the journey, the skin and feathers are either contaminated from the bird's own droppings or, if the flooring on each tier is perforated, birds below may become cross-contaminated. These problems are exacerbated under wet weather conditions, which tend to spread fecal material among the birds.[150]

It is often assumed that the stress involved in transportation increases the likelihood that birds will become shedders of *Salmonella*. Experiments on simulated transport stress, involving crowding, movement, and chilling, showed that stress increased the proportion of salmonella shedders from 33% to 54% within 4 hours, but the level declined thereafter.[121] An earlier study, with longer holding periods was unable to demonstrate any increase in the proportion of birds shedding salmonellas, although the organisms could be isolated more frequently from the body cavity and liver, suggesting that systemic infection had occurred.[125] Inadequate cleaning and disinfection of vehicles and transport crates after use appears to be a common problem. In one study, 46% of birds from a salmonella-free broiler flock became contaminated after being loaded into contaminated crates.[122] With the older type of system in which the crates are fixed to the vehicle, cleaning must be done manually by hosing with chlorinated water, for example, and insufficient time may be devoted to this task.[82] For crates that can be cleaned individually, away from the transporter, an automated system that involves a soaking period and machine washing, together with the use of a sanitizer, is preferred.

In modern processing plants, advances have been made in relation to the hanging of birds on the processing line. Crate design has been improved and access to the birds by the operatives has become easier. Nevertheless, unloading inevitably causes a degree of struggle and wing-flapping, which scatters dust and microorganisms, including any foodborne pathogens present.[106,153] It is necessary for this part of the operation to be physically separated from the remainder of the process.

Stunning of the birds, or killing by electrocution, is usually carried out with a waterbath stunner, and the head should be only partly immersed to avoid inhalation of contaminated water. In practice, some of the birds do inhale a small amount of water, which may penetrate into the lung cavity.[41] This is unavoidable at present, although the problem can be minimized by ensuring a constant overflow from the stunner bath. It would be eliminated entirely by the use of gas stunning. Cutting the neck to bleed out the carcass is not associated with any severe microbiological problem, although, with high-rate processing, there is no opportunity for heat treatment of the knife blade between individual birds. Cross-contamination can be reduced, however, by irrigating the rotating blade continuously with a stream of chlorinated water.[82]

After bleed-out, carcasses pass into the scald tank, where the hot, circulating water removes large numbers of microorganisms. It has been estimated that each carcass contributes about 10^9 organisms to the water, as it passes through the system.[92] Some of the older literature[63,137] indicates that birds could inhale water during the scalding process, leading to contamination of internal organs. This should not occur in birds that have been properly stunned and bled. Inevitably, the scald water becomes heavily contaminated with microorganisms but conditions are such that, after an initial build-up, the number of viable organisms will remain relatively constant over the working period.[85] Fresh water is added continuously to replace that removed by the birds and some processors maintain an overflow, which is required by law in the US. This overflow is generally too small to reduce microbial numbers in the water. The most important factor affecting microbial levels is the scald temperature.

Temperatures used for scalding poultry depend mainly on the required type of end-product. For the fresh, chilled market, a "soft" or semi-scald at 50°–52°C is necessary because this ensures that the cuticle is not loosened and subsequently damaged during defeathering, and it avoids any severe discoloration of the skin when carcasses are air chilled. The problem does not arise with carcasses that are water chilled and frozen and that acquire a surface layer of fine ice crystals. In this case, a "hard" or sub-scald at 56° to 63°C is used because feather removal is facilitated at the higher temperatures. At 50°C, bacterial survival is much greater in the scald water, and organisms such as *Salmonella* may persist long enough to cause cross-contamination of carcasses.[21] For example, a $D_{52°C}$ value of 150 seconds was reported for a strain of *Salmonella typhimurium*,[94] whereas the corresponding value at 62°C was only 8 seconds. Even at the highest temperatures used, there would be little effect on bacterial spores, including those of *C. perfringens*,[92] whereas highly heat-sensitive organisms such as *Pseudomonas* spp. are readily destroyed, even at 50°C.[4] Because of the large number of microorganisms being added to the scald water, this stage in poultry processing is inevitably an important site of cross-contamination.[72,94] Alternatives to conventional immersion scalding include spray or steam scalding and combined scalding and plucking, in which hot water sprays are used. Spray scalding has a higher water requirement and can have adverse effects on the appearance of carcasses. The use of steam is unsuitable for carcasses being produced for the chilled-product market because of damage to the outer cuticle.

A different approach to controlling microbial levels in scald water is to continuously add an antimicrobial chemical. Chlorine would be ineffective because of rapid inactivation, but 0.1% acetic acid markedly reduced $D_{52°C}$ values for *Campylobacter jejuni, S. newport,* and *S. typhimurium*.[105] Microbial survival is also related to the pH value of scald water, which is consistently around 6.0 because of dissociation of ammonium urate that is present in poultry feces. Experimental addition of sodium hydroxide or sodium carbonate increased the pH value to 9.0 ± 0.2 and reduced the $D_{52°C}$ value for *S. typhimurium* from 34.5 to 1.25 minutes.[52] These findings apply only to microorganisms in the water. Generally, organisms attached to the skin of the birds are more protected from the effects of heat and chemicals. Even at a concentration of 0.5%, acetic acid had little effect on carcass contamination, and the same was true for pH adjustment of scald water.[12,53]

Mechanical removal of the feathers from freshly scalded carcasses involves two particular problems. One is due to extensive aerial dispersion of organisms in the vicinity of the machines; the other involves microbial growth in the machinery and can lead to measurable increases in carcass contamination. Cross-contamination has been studied with the aid of a readily identifiable "marker" organism, a strain of *E. coli* K12, that can be detected on a highly selective isolation medium. Experiments have shown that, during defeathering, the "marker" can be transmitted to at least 200 birds following one that had been deliberately inoculated.[78,140] Organisms appear to spread mainly from the surfaces of the birds and not from extruded feces.[94] It is important that the scalding and plucking processes are carried out in a well-separated area of the processing plant to minimize the opportunities for microbial dispersion.

The defeathering machines are necessarily sited close to the scald tank so that feathers can be removed while the carcasses remain warm. Inside the machines, however, conditions are warm and moist and therefore favorable for microbial growth. Also, the rubber "fingers" harbor microorganisms and are particularly difficult to clean and disinfect properly. In addition, the "fingers" soon become worn and cracked, thus allowing organisms to penetrate below the surface, where they are relatively well protected. Surprisingly, the organisms that appear to flourish best under these conditions are staphylococci, especially *S. aureus* and *S. sciuri*.[76,77] The former, in particular, is not noted for its ability to compete with other types of bacteria. In this context, *S. aureus* has been studied extensively and some strains are known to persist in the defeathering machines for months or even years, because routine cleaning and disinfection are unable to eliminate them.[76] Such strains appear to be "endemic" to the processing plant in question. The organisms tend to be more resistant to chlorine than other strains and often show an unusual clumping morphology, together with the formation of extracellular slime.[15,75] It is thought that these properties may account for the greater chlorine resistance. The ultimate origin of "endemic" *S. aureus* remains unclear, although strains are most likely to be brought into the processing plant by the birds, albeit in low numbers. While most strains of *S. aureus* from poultry do not produce any detectable enterotoxins, some isolates from defeathering machines have been shown to produce types C and D toxins.[76]

Growth of staphylococci in defeathering machinery sometimes yields counts of *ca.* 10^7 cfu $swab^{-1}$ and increases levels of carcass contamination. The plucking process can also increase the proportion of birds contaminated with salmonellas.[19,88,99] At present, there is little that can be done to control the microbiological problems associated with defeathering, although the more modern machines are easier to clean and disinfect. A radical new design would be needed to overcome the problems described above.

Feather removal is more difficult in the case of ducks. The birds are scalded at 60°C, machine plucked, and then immersed in molten wax at *ca.* 90°C, which is hardened by subsequent immersion in cold water. The wax is stripped from the birds by hand or machine, thus removing the fine feathers. After use, the wax is melted again and recycled. The high temperature treatment appears to have a beneficial effect on the microbial quality of the final product, and water-chilled ducks were found to carry very low numbers of coliform bacteria.[10] For all types of poultry, it is considered advisable to pass the birds through a spray washer after the plucking process is complete.

Prior to evisceration, the head and feet are removed from each carcass; then the birds pass through a series of machines, each of which carries out a specific operation leading to removal of the viscera. In low-throughput processing plants, the same operations may be carried out manually. For both types of system, there are opportunities for carcass contamination to increase and for cross-contamination to occur. With manual evisceration, the extent of these problems depends upon the care taken by operatives. In fully automated plants, the machines must be set carefully and adjusted as required. The type of equipment used is also an important factor. Some machines cause breakage of the intestines and hence contamination of carcasses with gut contents. This is because the machines do not adjust automatically to the varying size of individual birds. Once the viscera have been exposed, the birds are ready for inspection and then removal of edible and inedible parts. However, new methods of evisceration and giblet harvesting are now available. These involve immediate separation of intestines and giblets from the carcasses and transfer of the viscera to a separate, parallel line for official inspection. This approach avoids much of the problem of carcass contamination, because the viscera are no longer in contact with the bird. Depending on the type of equipment used, some degree of cross-contamination is likely to occur through contact with machinery, implements, and the hands of operatives and has been demonstrated previously with the use of "marker" organisms.[78,131,140] Some items of equipment, such as the head puller, are known to be a source of salmonella contamination, although the problem can be minimized by continuously spraying the functional parts with water containing at least 40 mg l^{-1} of free available chlorine.[3]

Modern poultry meat production is a relatively wet process because water sprays are commonly used in the eviscerating machines, and carcasses may be spray washed at more than one stage in the evisceration process. In those countries that permit the use of chlorine, concentrations of 20–50 mg l^{-1} or more of available chlorine may be employed in the washers. Carcasses are finally spray washed, when in the "oven-ready" form, to ensure that all visible soiling from spots of blood or feces has been removed. Mechanical washers clean both the outside and inside of the bird by lowering a spray nozzle into the body cavity at the same time as high-pressure jets wash the outer surface. The cleaning process also removes some of the microbial contaminants present, but the effect is limited due to microbial attachment to the skin. Removal of microorganisms is best when carcasses are washed as soon as possible after contamination and before attachment can occur.[100] With a "marker" strain of *E. coli*, it has been shown that spray washing only at the end of evisceration reduced neither the proportion of carcasses that acquired the "marker" nor the numbers of organisms being transferred.[77] In this study, the water contained 20 mg l^{-1} of free available chlorine. While the use of chlorine has little direct effect on carcass contamination, it does control the build-up of microorganisms on equipment and destroys any spoilage bacteria that may be present in the plant water supply. *Pseudomonas* spp. are more resistant to chlorine than many vegetative bacteria and may not be eliminated during normal water works treatment.

In high-throughput processing plants, scalding, plucking, evisceration, and washing of carcasses are complete within a matter of minutes, and thus there is little loss of body heat within this period. Carcass temperatures above 30°C can be expected prior to chilling. Prompt and efficient chilling of the bird is essential to prevent growth of mesophilic pathogens and to limit multiplication of psychrotrophic organisms such as spoilage pseudomonads. There are two main types of chilling systems, one involving immersion of carcasses in cold water and the other requiring the use of cold air, with or without wetting the birds to enhance the rate of cooling through evaporation (evaporative cooling).

All poultry chilling is essentially a two-stage operation, in which the first stage precedes grading and packaging and aims to chill the product below 10°C to avoid any problem from microbial growth. Then, the bird is either graded and packaged as a whole carcass or used to prepare cut portions, after which the product is either frozen or chilled to 0° to 2°C. Water immersion chilling is a continuous process and carcasses move through one or more large tanks of water, to which ice or chilled water are added, as required. The water is kept in a state of constant agitation to facilitate cooling of the carcasses. The agitation also removes a proportion of the contaminating microorganisms. Because organisms are continuously being added to the chill water, it is important to prevent build-up over the working day by controlling water usage and temperature. Adequate use of fresh water is essential to the cooling process and also prevents the water from reaching a temperature at which considerable microbial growth could occur. Using a mathematical model designed to study the interaction of factors involved in water chilling,[58] it was shown that microbial numbers in the water would be unlikely to exceed 10^5 ml^{-1} and could be substantially less, when chilling systems are suitably controlled. Observations on commercial systems supported this conclusion.[13,73] In the chilling systems commonly used, carcasses are moved through the water, either in the same direction as the water flow (through-flow) or against it (counterflow).

Within the European Union (EU), it is mandatory to use only the counterflow type of chiller, in which carcasses meet the cleanest water as they leave the system. EU regulations (Table 20-3) specify the amount of water to be used for different sizes of carcass; how the water should be divided between chill tanks, if more than one is used; the temperature of the water at the carcass entry and exit points; and the maximum residence time for carcasses in the first part of the system. In addition, there are specific requirements relating to cleaning of carcasses prior to chilling.

Countries outside the EU may use a different mode of operation or one that is less detailed. In adequately controlled chilling systems, the washing effect on carcasses leads to a net reduction in microbial contamination and reduces both aerobic plate counts and counts of coliform bacteria by 50% to 90%.[16,74,133] Levels of salmonella contamination may also be reduced but not, usually, the proportion of salmonella-positive carcasses. Where no reduction in count has been observed, either the chilling system was not properly controlled or carcass contamination prior to chilling was unusually high.[64] An obvious disadvantage of this method of chilling is the opportunity for cross-contamination because large numbers of carcasses are chilled together in the same tank. The problem can be minimized by superchlorination of the chill water.[73] For this purpose, it is necessary to maintain a residual of 45–50 mg l^{-1} of total available chlorine, which eliminates virtually all viable organisms from the water (Table 20-4). Continuous immersion chilling is a rapid and highly effective means of cooling small carcasses, such as those of chickens. With turkeys, some of which weigh 20 kg or more, longer periods of chilling are needed and the continuous process is followed by the use of static slush-ice tanks, which further reduce carcass temperatures and ensure a tender product prior to freezing. Growth of psychrotrophic bacteria during prolonged water chilling can be controlled by adding chlorine to the process water.

Table 20-3 Operational Requirements for Water Immersion Chilling of Poultry in the European Union

Type of Chilling System	*Counterflow*
Max. water temp. at carcass entry point	16°C
Max. water temp. at carcass exit point	4°C
Total water throughput,	
up to 2.5 kg carcasses	2.5 l/carcass
2.5–5.0 kg carcasses	4.0 l/carcass
above 5.0 kg carcasses	6.0 l/carcass
Water throughput in last tank, if more than one tank,	
up to 2.5 kg carcasses	1.0 l/carcass
2.5–5.0 kg carcasses	1.5 l/carcass
above 5.0 kg carcasses	2.0 l/carcass
Time limit for carcasses in first part/tank	30 minutes

Source: Data from European Union Poultry Meat Hygiene Directive (originally 71/118 EEC).

Chilling carcasses in cold air rather than by water immersion is used for both chickens and turkeys and may be carried out as a batch process or in a continuous air-blast system, with or without a fine water spray at the beginning of the process (evaporative cooling). Because there is no washing effect, air-chilled carcasses tend to carry more microorganisms than those that are water chilled in a properly controlled system.[21,89,138] Although relatively dry in appearance initially, the carcasses have a similar shelf life to that of water-chilled birds, when both are sold as packaged products. Air chilling is preferred for some products because there is less absorption of extraneous water, and the process is less likely to cause microbial cross-contamination. Nevertheless, mi-

Table 20-4 Control of Microbial Contamination in a Water Immersion Chilling System by Superchlorination

Chlorine[a] Concentration mg l^{-1}	*Unit 1*		*Unit 2*		*Unit 3*	
	TVC,[b] 1°C	*Coliforms*	*TVC, 1°C*	*Coliforms*	*TVC, 1°C*	*Coliforms*
0	2.7	4.0	3.8	3.7	2.6	3.1
10–15	2.7	2.9	1.9	1.2	NF[c]	1.2
25–30	1.9	0.1	NF	NF	NF	NF
45–50	NF	NF	NF	NF	NF	NF

[a] Total residual chlorine. Water usage 2.5 l carcass^{-1} (total). Samples taken at 30-minute intervals over a period of 4.5 hours. All counts are expressed as mean $\log_{10}$ cfu ml^{-1}.

[b] TVC = total viable count.

[c] NF = not found.

croorganisms may circulate in the currents of cold air, and carcasses are often touching one another in the chiller, so that some microbial transmission is inevitable. In rare instances, carcasses or cut portions are chilled by means of cryogenic methods involving liquid nitrogen or carbon dioxide. The use of carbon dioxide "snow" for secondary chilling causes crust-freezing of the product, which is not favored in the EU. Ultimately, equilibration occurs, giving a surface temperature of *ca.* –2°C and an extended shelf life.

The grading, trussing, and packaging stages follow chilling. These involve further handling of the product, possible cross-contamination from hands and equipment, and even growth of psychrotrophs if there are delays before chill storage or freezing. The freezing process can reduce the number of viable organisms present,[113] especially those of Gram-negative genera, but Gram-positive bacteria such as *S. aureus* and bacterial spores are largely unaffected.

Chilled carcasses that are not required for the whole-bird market are used to prepare cut portions. In the larger chicken processing plants, portioning is a highly automated operation, while turkeys are generally cut by hand. In both cases, there is manipulation of the meat and exposure of new cut surfaces, with associated microbial contamination and cross-contamination. It is important that the cutting environment remains cool and dry to minimize any growth of spoilage bacteria.

20.3.5 Development of Hygienic Processing Machinery

In relation to product hygiene, the main priority in poultry meat production is to reduce the incidence of carcasses contaminated with *Salmonella* and/or *Campylobacter* species to the lowest possible level. While any degree of contamination with these and other foodborne pathogens is undesirable, the nature of the present process provides no fully effective means of removing or destroying contaminants once they are acquired by the carcasses. Future improvements in hygiene control will depend upon the introduction of new equipment, involving fresh concepts. However, although hygiene control is acknowledged to be important to equipment manufacturers, it is not the first priority and, understandably, cost-effective operation of machinery is the prime consideration. Generally, the legislation in different countries does not include any specific requirements relating to the type of equipment that processors use.

Despite the lower priority given to hygiene control, several new developments have occurred in recent years. These include multistage scalding, the new type of evisceration system referred to above, better equipment for cleaning and disinfecting live-bird delivery crates, and cleaning-in-place systems for rotating evisceration equipment. Although they are not yet used universally by the poultry industry, most of the newer machines are gradually gaining acceptance. The question arises, how effective are these kinds of equipment in reducing carcass contamination? The question is difficult to answer because old and new machines cannot usually be compared at the same time and place, using birds from a common source. However, it is claimed that counterflow, multistage scalding reduces microbial contamination of carcasses by about 60%.[154] The system has the advantage that carcasses meet progressively cleaner water during the scalding process and water in the different sections can be changed whenever required. The newer type of evisceration equipment provides more controlled opening of carcasses and transfer of the viscera to a separate, parallel line, with separation of hearts, lungs, and livers. Inevitably, the process leads to less spillage of gut contents, and therefore, lower levels of carcass contamination.

In a study of counterflow scalding operated in conjunction with a post-scald, 60°C spray wash, significant reductions in carcass contamination were demonstrated.[57] On the other hand, any benefit in reducing salmonella contamination was lost during water chilling. This underlines the need for improvements in hygiene control at all stages of the process. While improvements in processing equipment will continue to reduce the microbial load on carcasses, such developments are unlikely to lead to the removal of all contaminants or avoid the problem of cross-contamination. However, more fundamental changes in machinery design and mode of operation could well conflict with the interests of processors in maintaining efficiency, speed, and product yield.

20.3.6 Application of the Hazard Analysis Critical Control Point (HACCP) System

The HACCP concept provides a systematic means of identifying, evaluating, and controlling the microbiological hazards that arise in operations concerned with food production, processing, or handling. It also involves specifying the control criteria and establishing rapid monitoring procedures so that corrective action can be taken immediately, if control is lost. Detailed records, including those of any corrective action, are essential, and the effectiveness of the control system as a whole needs to be verified, with all possible hazards identified, when the controls are operational. Both principles and specific applications are described by the International Commission on Microbiological Specifications for Foods.[55] Particular advantages of the HACCP approach are its preventive nature, dealing with hazards before they arise, and the fact that the whole process is covered comprehensively. Thus, the system is a powerful tool for ensuring product safety, and it is a company responsibility to implement and maintain a HACCP-based control program as part of the quality assurance scheme. These activities cannot be a function of the regulatory authority, and a more appropriate role for regulators is to ensure that the HACCP system is functioning effectively (verification).

HACCP principles can be applied at all stages in the poultry meat production chain, and in the UK, for example, a risk analysis approach is increasingly being encouraged to control microbial hazards associated with rearing and slaughtering of poultry.[119] In consequence, a Hygiene Assessment System (HAS) has been introduced as a means of monitoring hygiene standards in processing plants and identifying any premises where conditions are unsatisfactory.[127] The assessment is carried out by the Official Veterinary Surgeon and must take place while the processing plant is in operation, preferably at normal line speed. The aspects covered in the assessment include antemortem handling and inspection of birds, processing conditions, personnel and hygiene practices, maintenance and hygiene of the premises, and general conditions and management of the plant. Scores are awarded in one of four categories in which "a" represents the highest standard and "d" the worst. For each section of the assessment, the component scores are added together to give a subtotal. Then, a conversion factor is applied so that the final figure more accurately reflects the impact on the hygiene status of the final product. The weighting given to the various categories is, in percentage terms, processing conditions, 45; personnel and hygiene practices, 25; antemortem handling and inspection, 10; and general conditions and plant management, 10. The emphasis given to processing conditions indicates the importance of processing equipment and its mode of operation in determining the microbiological condition of finished carcasses.

The HAS approach attempts to introduce a degree of objectivity in assessing plant performance and is proving to be of value for this purpose. It concentrates effort in those areas that are most likely to benefit product safety and provides a yardstick by which the overall performance of the industry can be judged. For individual processors, the system is a tangible inducement to attain the highest level of performance, and it could be adapted for computer-assisted control of hygiene in the processing plant. Processors who are applying HACCP principles are likely to achieve a high score in the HAS. Generic HACCP schemes for poultry processing have been described,[55,95] but these "blueprints" serve merely as guides. Experience shows that no two processing plants are identical in all respects. Consequently, processing conditions will vary from one establishment to another and each processing line requires its own hazard analysis.

Regarding the need to control gross contamination of carcasses, only chilling can be considered as a CCP1 (complete control) because it serves to prevent any problem from microbial growth. Spray washing processes are CCP2s since they only reduce carcass contamination. However, chilling is not a critical control point (CCP) for the incidence of salmonella-contaminated carcasses. In the case of water immersion chilling, chilling may even favor cross-contamination, if the process is not strictly controlled, preferably with the use of superchlorinated water. Cross-contamination can involve very small numbers of organisms. It occurs continuously throughout the process and is only partly reduced by introducing conventional control measures (see below). In this respect, the CCPs given in generic plans are unlikely to have much effect unless a decontamination step is introduced. Scalding, for example, removes large numbers of microorganisms from the freshly slaughtered birds but, in doing so, provides conditions that favor the transmission of any pathogens present. Scald temperatures of 60°C or above will destroy many of the vegetative organisms in the water, including salmonellas, but are rarely used in practice because of possible cooking effects and the need to use lower temperatures for carcasses being prepared for the chilled market. Therefore, scalding is a CCP in relation to gross contamination, because there is a net removal of organisms from the carcass surface. On the other hand, this part of the process is a significant cause of salmonella cross-contamination, and the problem is not readily avoided.

The evisceration stages pose similar problems. Careful setting of automatic machinery and resetting for flocks of different average bird size will minimize gut breakage and thus reduce fecal contamination of carcasses (CCP2). Nevertheless, many of the machines in current use cause some breakage of the intestines, regardless of the care taken in adjustment; hence, a degree of cross-contamination is to be expected.

It follows from the above that, whereas CCPs can be identified to control gross contamination, including that involving spoilage bacteria, there appear to be no CCPs in the basic process that would prevent or consistently reduce the incidence of cross-contamination with minority foodborne pathogens. This does not mean, however, that Good Manufacturing Practice (GMP) cannot combine to limit the spread of hazardous organisms when applied to the process as a whole. Examples are effective cleaning and disinfection of equipment and the processing environment after one processing period and before another, and attention to hygiene of personnel. GMP is seen as a necessary part of the HACCP program in poultry processing plants.[39] In attempts to identify and control those parts of the process where cross-contamination is known to occur, the readily identifiable enteric "marker" organism described earlier has been used to inoculate carcasses, equipment, or working surfaces.[82] The spread of the organism was then followed both before and after introducing additional hygiene control measures, which included the application of chlorinated water sprays to prevent a build-up of microorganisms on equipment, increasing chlorine concentrations in process water, and eliminating all unnecessary carcass contact surfaces. The results showed that cross-contamination could be reduced (Table 20-5) and even prevented at some points in the process.

Another study[83] investigated the effect of similar controls on the contamination of carcasses with naturally occurring campylobacters. It was found that some 95% of birds from 15 flocks yielded positive neck-skin samples after exsanguination, but processing reduced levels of campylobacter contamination by 10- to 1,000-fold and contamination was significantly lower following changes in the process to improve hygiene control. In practice, however, the reduction was relatively small and unlikely to affect exposure of consumers to these particular organisms.

20.3.7 Decontamination of Processed Carcasses

An effective and acceptable means of inactivating foodborne pathogens that are present on finished carcasses would be clearly advantageous and could provide the processor with a CCP to counteract the problem of product contamination during processing. However, poultry meat is light in color and relatively bland in flavor, and is easily affected by the kinds of antimicrobial treatment that may be needed. Thus, it appears to be difficult to find a treatment that would be sufficiently effective, but without any adverse effect on the appearance, odor,

flavor, or nutritional properties of the meat. Undesirable residues would also need to be avoided, as would any damage to the environment in disposing of waste treatment material. In addition, the proposed treatment must be acceptable to both consumers and legislators.

Despite the above difficulties, many attempts have been made to develop a suitable means of product decontamination. These have included a variety of physical and chemical methods, some of which were proposed for red meat, but may be also applicable to poultry.[24] Many of the treatments were purely experimental and have not been tested under commercial conditions. The physical methods include use of steam or hot water, high-intensity visible light, microwaves, high voltage pulsed electric fields, oscillating magnetic field pulses, high pressure, ultrasonic energy, and negative air ions. Physical methods have the advantage of avoiding any chemical residues but, to be effective against microbial contaminants, some of them could cause undesirable changes in the meat. A case in point is the application of steam, but cooking of the meat can be avoided by repeated exposure of the meat for very short periods of time. In one approach,[87] meat samples were subjected to superheated steam for 52 milliseconds or more in repeating cycles. The meat was then cooled rapidly by re-evaporating the condensate on the meat surface back into vacuum. Following inoculation, a reduction in listerias of almost 4 $\log_{10}$ units could be achieved with this method, without any visible effect on the meat. The steam treatment was carried out in a model system and was not ready for commercial use at that time.

Other proposed treatments include various chemicals, antibiotics, bacteriocins, and bioactive peptides. Chemical treatments (Exhibit 20-1) are relatively easy to apply while carcasses remain on-line and utilize either immersion or spraying processes. At present, the main contenders appear to be lactic acid and trisodium phosphate, both of which are acceptable for food use in the US and other countries, but have yet to be fully approved in the EU for treating poultry carcasses. The effectiveness of organic acids in reducing meat contamination is known to depend on the method of application, the concentration used, the time and temperature of treatment, and the extent to which microbial contaminants have become attached to the meat surface prior to treatment.[128] When carried out under optimal conditions, decontamination can be expected to reduce or even eliminate low numbers of foodborne pathogens. The process should be regarded as an adjunct to good processing hygiene rather than a substitute for it. In a comparison of nine different decontamination treatments involving a 20-second period of immersion,[1] trisodium or tripotassium phosphate (10%) were the most effective, reducing skin contamination by 10- to a 100-fold. However, the

mechanism of the effect remains uncertain. Likely factors include the high pH (*ca.* pH 12.0), the detergent action, and detachment of microbial contaminants from the carcass surface.

The treatment that would be most effective in destroying foodborne pathogens on poultry meat is the use of ionizing radiation. The process is regarded as entirely safe as far as the product is concerned and it is not associated with any toxicological hazards or nutritional or microbiological problems.[147] At dose levels considered suitable for poultry (up to 3.0 kGy for chilled products), it has minimal effects on the sensory properties of the meat. Higher doses can be used for frozen poultry, depending on the temperature at which the product is treated. For whole carcasses, the high penetrative capability of gamma rays would appear to be needed but, for cut portions, it would be adequate to use the less penetrating electrons produced by linear accelerators. A particular advantage of irradiation is that it can be applied to products that are already packaged, thereby avoiding any possibility of post-treatment contamination. Some evidence suggests that the treatment dose for fresh chicken and turkey should not exceed 2.5 and 1.5 kGy, respectively, to avoid flavor changes in the cooked meat (Table 20-6). Such changes can only be avoided by treating the product in the frozen state. At 2.5 kGy, salmonellas would be virtually eliminated because the organisms are generally present on carcass meat in only low numbers, 90% of carcasses carrying <100 cells 100 g^{-1} of skin.[93] With irradiated, frozen carcasses, there is a further lethal effect of frozen storage.[91]

Irradiation may also double the shelf life of chilled poultry and *Pseudomonas* spp. the main spoilage organisms of meat stored aerobically under chill conditions are readily killed by the treatment. At the low-dose levels being recommended, however, a small proportion of the *Pseudomonas* population will usually survive and ultimately multiply to cause spoilage in the normal manner. It is rare to find a different spoilage microflora, although off-odors resulting from growth of organisms that are now classified as *Acinetobacter/Psychrobacter* spp. have been reported.[56]

Despite the considerable advantages of irradiation with regard to product safety and shelf life, the logistics of introducing the process would require careful consideration. Installing a facility for gamma irradiation would cost several million pounds (UK) or dollars (US); it may be necessary to establish regional treatment centers that could be shared, rather than plants belonging to individual companies. This approach has the disadvantage of incurring additional transportation costs. There is also the question of whether sufficient cobalt 60 would be available to satisfy the demand or suitable electron accelerators could be developed for whole carcasses. Regardless of feasibility, there is still the barrier of consumer resistance to food irradiation in many of the developed countries. Frequently, it is found that consumers do not understand the technology and are afraid that treated food will be hazardous, less nutritious, and of lower sensory quality.[62] In the US, consumers appear to take a more positive stance and, in one survey, about half of those questioned stated that they would be willing to purchase irradiated foods.[17] This contrasts with the situation in the UK, where neither the public nor the food industry appears to show any real interest in the process, and considerable effort would be required to inform the public of the specific advantages of irradiation, while allaying those fears that are based on common misconceptions.

Table 20-6 Doses of Ionizing Radiation for Different Kinds of Meat, Above Which Flavor Changes in the Cooked Meat Were Detectable by a Taste Panel

Type of Meat	*Dose (kGy)*
Turkey	1.50
Pork	1.75
Beef	2.50
Chicken	2.50
Lamb	6.25

Note: Samples in gas-impermeable pouches were irradiated at 4.4° to 10°C.

20.4 RAW POULTRY PRODUCTS

Raw poultry meat is available in various forms, whether fresh or frozen, and includes whole carcasses and a variety of cut portions, with or without skin, to suit consumer demand for convenience items. Carcasses may also be self-basting or with added salt, polyphosphate, or herbs and spices, etc. Some, but not all carcasses, may include giblets and these are sometimes available separately, especially liver. In some countries, there is a demand for uneviscerated carcasses, including those that are hung like game birds, to enhance meat flavor. Cut portions include breast meat and thighs (with or without bone), drumsticks, and wings. After por-

Next Page

tioning in the processing plant is complete, fragments of meat remain on the residual bones and are harvested by machine. The mechanically separated meat (MSM) is in a finely comminuted state, but is one of the most important by-products and is used in soups, meatballs, patties, and various emulsion-type products, such as salamis and frankfurters.

As with other flesh foods, the bacteria that multiply most rapidly on chilled poultry meat are pigmented and nonpigmented strains of *Pseudomonas* spp., including *P. fluorescens, P. fragi,* and *P. putida.* These are accompanied by lower numbers of *Acinetobacter* spp., *Psychrobacter immobilis,* and an organism now recognized as a nonmotile form of *P. fragi.*[26] All these bacteria grow well on cut muscle surfaces, where moisture and nutrients are abundant, and some of the pseudomonads produce characteristic off-odors when populations reach *ca.* 10^8 cfu g^{-1}. Because whole carcasses first develop off-odors from the neck skin, some producers remove as much of this tissue as possible to gain a further day of shelf life. The mechanism of bacterial spoilage has not been determined for poultry meat, but is assumed to be the same as that of red meat. Thus, the spoilage pseudomonads are likely to grow preferentially on muscle glucose and, when this is exhausted, they will ultimately utilize amino acids, some of which can give rise to malodorous, volatile compounds that are associated with typical spoilage.

Much of the poultry meat sold in supermarkets is prewrapped, the immediate objective being to prevent drying of the surface and hence loss of weight, as well as to avoid damage to the product and microbial cross-contamination. In the case of air-chilled carcasses, the surface is relatively dry after chilling, with a reported water activity (a_w) of 0.970, while carcasses chilled by water immersion were found to have an a_w of 0.996.[114] After packaging, however, there was no significant difference in shelf life because, in the drier carcasses, moisture migrated to the surface from the deeper tissues.

Under chill conditions, storage temperature is the principal factor that determines shelf life by virtue of its effect on the growth of spoilage bacteria. The shelf life of whole carcasses packaged in oxygen-permeable film is usually 12 to 14 days at 1°C. With poultry sold unwrapped in a butcher's shop, for example, the drying of the surface may help to prolong shelf life, provided that chill storage is maintained. However, whole carcasses are unlikely to dry out uniformly and moist areas tend to remain. The most effective means of extending shelf life under aerobic conditions is to keep the product as cold as possible without causing it to freeze, ie, *ca.* –1°C. The effect of temperature on the shelf life of air-chilled eviscerated turkeys is shown in Figure 20-2.

Shelf life is also affected by the nature of the packaging film, which can modify the composition of the gaseous environment within the pack. All films will have some effect in this respect, and those that have low permeability to oxygen and carbon dioxide can significantly extend shelf life. In vacuum packs, with low-permeability film, oxygen is consumed during chill storage, while carbon dioxide accumulates due to residual tissue respiration and microbial metabolism. The increase in carbon dioxide inhibits growth of aerobic spoilage bacteria[25,43] and extends shelf life by this means. Even atmospheres containing only 3% carbon dioxide have been found to delay growth of pseudomonads on red meat,[35] although, at any concentration, the inhibitory effect depends upon maintenance of chill conditions. The increased level of carbon dioxide allows slower growing microorganisms that are unaffected by the prevailing conditions to become predominant. Eventually, these organisms will spoil the product, with off-odors that are less objectionable than those produced under aerobic conditions. The causative organisms include *Carnobacterium* spp. and other lactic acid bacteria and, less frequently, *Brochothrix thermosphacta,*

The carcasses were stored in oxygen-permeable polyethylene bags. *Source:* Data from E.M. Barnes, et al., The Effect of Storage Temperature on the Shelf-Life of Eviscerated Air-Chilled Turkeys, *British Poultry Science,* Vol. 19, pp. 77–84, © 1978, Carfax Publishing Co.

Shewanella putrefaciens, psychrotrophic coliforms, and *Aeromonas* spp.

There is only limited use of vacuum packaging for raw poultry meat and other systems of modified atmosphere storage are more common. One such system involves bulk packaging some 30 kg of product in an oxygen-impermeable bag, which is then evacuated and back-flushed with 100% carbon dioxide before being sealed. The pack can be delivered to retail stores and the unwrapped carcasses removed and displayed individually. Within the pack, a shelf life of 18 to 21 days at -2 to +1°C can be expected.[139] Gas-tight storage cabinets are sometimes used for the same purpose. In this case, each product is wrapped in a film that allows inward transmission of carbon dioxide. The benefits of storing poultry meat in atmospheres enriched with carbon dioxide have been known for many years and followed from the classical work of Ogilvey and Ayres.[103] Cut portions of chicken were stored either in air or air containing different concentrations of carbon dioxide. Within the range 0% to 25% carbon dioxide and at a storage temperature of 4.4°C, the ratio of shelf life in carbon dioxide to that in air ("storage index") was found to be a linear function of carbon dioxide concentration. The carbon dioxide affected both the lag phase and doubling time of the bacteria present.

Retailing of red meat in modified atmosphere packs (MAP) involves gas mixtures containing a high concentration of oxygen to maintain and enhance the red color of the meat due to formation of oxymyoglobin. Inclusion of oxygen is unnecessary for poultry meat, which is naturally much lighter in color, and most packs of poultry meat sold in this form do not include added oxygen.[22] However, 100% carbon dioxide would be unsuitable for retail packs because, at this concentration, some of the gas would dissolve in the tissues, causing the pack to collapse. Concentrations of 20% or more in nitrogen, for example, are usually employed.

Some researchers prefer to use mixtures of carbon dioxide and air, and this may be necessary for duck meat to safeguard the appearance of the product.[79] In a study of chicken breast and leg portions held at 2°C in atmospheres containing 0% to 80% carbon dioxide in air, aerobic plate counts were 10,000-fold higher after 14 days for portions held in air than those stored under 80% carbon dioxide.[50] The carbon dioxide-stored product was rated more highly for raw meat odor and overall acceptability by a sensory panel, and eating quality of the cooked meat remained acceptable for up to 35 days. An interesting feature of portions held in 80% carbon dioxide was a residual inhibitory effect on microbial growth when the product was transferred to aerobic conditions. This was not observed with lower concentrations of carbon dioxide. The change of gaseous environment may have extended the lag phase of the spoilage bacteria or the effect may have been due to the slow release of carbon dioxide dissolved in the tissues.

Only recently have large amounts of raw chicken been sold at retail in MAP because, previously, costs were too high. This type of presentation has been used more often for turkey and duck, which command a higher price. Specific gas mixtures are required for these meats. With duck portions stored at 1°C in 20% or 80% carbon dioxide in nitrogen, an unacceptable waxen or milky appearance has been observed in the skin.[80] The same effect occurred in pure nitrogen, but not in 20% carbon dioxide in air. The latter gas mixture extended shelf life from 14 to 21 days on the basis of raw meat odor and cooked meat flavor. Turkey, on the other hand, is particularly susceptible to oxidative changes during chill storage, and breast fillets were best packaged without air.[79] Fillets held at 1°C in 30% carbon dioxide in nitrogen showed no significant deleterious changes after 21 days.

20.4.1 Possible Hazards from Psychrotrophic Pathogens

Extending the shelf life of raw poultry by use of MAP raises the question of whether psychrotrophic pathogens that are always outgrown by spoilage pseudomonads under the usual aerobic conditions might multiply and reach hazardous levels when the pseudomonads and other aerobic spoilage bacteria are inhibited. The pathogens of concern include those strains of *Clostridium botulinum* that can grow and produce toxin down to 3.3°C, as well as *Listeria monocytogenes*, *Yersinia enterocolitica*, and *Aeromonas* spp. In relation to botulism, vacuum and gas packaged foods have a remarkable safety record, with only seven outbreaks occurring worldwide between 1960 and 1991.[116] Most of these involved smoked fish products and resulted from gross temperature abuse. Fresh meats in MAP, including poultry, would present a relatively low risk of causing botulism because of the normal conditions of chill storage, the presence of a competing psychrotrophic microflora, and a defined shelf life. Also, the ultimate safeguard is that poultry meat always will be cooked before consumption. A potentially different situation arises with some further-processed, ready-to-eat poultry products, which will be discussed in a later section.

Studies on the growth of other psychrotrophic pathogens on raw meats have been reviewed,[34] revealing some conflicting results in the literature. In general, however, the ability of the organisms to multiply will depend on conditions of temperature, meat pH, and competing microflora and MAP conditions do not appear to involve any additional hazard. At carbon dioxide concentrations above 75%, listerias, yersinias, and aeromonads tend to be inhibited on meats, while the higher the carbon dioxide concentration and the lower the pH and storage temperature, the greater is the growth inhibition of these organisms. Thus, holding chilled poultry under 100% carbon dioxide can be expected to prevent or retard any multiplication of vegetative, psychrotrophic pathogens. Even growth of psychrotrophic *C. botulinum* is likely to be delayed under these conditions.[30]

20.4.2 Uneviscerated Carcasses

In some countries, there is still a significant trade in chicken carcasses that have been plucked, but not eviscerated, by the producer. Subsequently, the carcass may be eviscerated by a butcher or in the kitchen of the consumer. Another, similar product is a special breed of turkey that is produced in the UK for the Christmas market. In this case, however, the carcasses are hung by the processor at 4°C for up to 2 weeks to allow flavor development and then eviscerated before distribution. Uneviscerated poultry, with head and feet still intact, are sometimes referred to as "New York dressed" (NYD), while carcasses from which only the intestines have been removed through a small opening are termed "effilé." The more traditional NYD carcass is less prone to spoilage than its eviscerated counterpart, as long as the carcass is kept cool and dry, with an intact skin. These conditions provide little opportunity for multiplication of the usual aerobic spoilage bacteria, and small processors can begin production well in advance of the Christmas season to meet demand. It has been shown[8] that NYD carcasses were still acceptable after 18 days at 4°C, while those that had been eviscerated initially were spoiled after little more than a week (Table 20-7). At lower temperatures, NYD carcasses could be expected to keep even longer.[6]

Table 20-7 Shelf Life of Eviscerated and Uneviscerated, Air-Chilled Chicken Carcasses Stored at 4°C. Mean and range indicated by ( ) of 10 carcasses in each case.[8]

	Time (days) to	
Type of Product	*Slight Off-Odor*	*Off-Odor*
Eviscerated, wrapped	5.6 (5–6)	7.6 (6–8)
Eviscerated, not wrapped	7.9 (5–11)	9.8 (7–13)
Uneviscerated, not wrapped	>18.0[a]	>18.0[a]

[a] Neither greening nor off-odors. Wrapped carcasses were held in food-grade "polythene."

Source: Data from E.M. Barnes and C.S. Impey, The Shelf-Life of Uneviscerated and Eviscerated Chicken Carcasses Stored at 10°C and 4°C, *British Poultry Science*, Vol. 16, pp. 319–326, © 1975, Carfax Publishing Co.

Spoilage of NYD poultry can be due to one of three possible causes. If the dryness of the surface is not maintained, aerobic spoilage bacteria will multiply and produce off-odors in the usual manner. Alternatively, carcasses kept uneviscerated for prolonged periods can develop a meat flavor that some individuals would find unacceptable, ie, a "gamey" or "gutty" flavor. The third, more common type of spoilage is due to microbial production of hydrogen sulfide in the intestines and diffusion into the musculature. At the surface of the carcass, in the presence of air, the hydrogen sulfide reacts with heme pigments of blood and muscle to form sulfur derivatives.[6] This leads to an unacceptable greening of the skin, a condition that is sometimes termed "greenstruck." The greening, which develops at a rate dependent on storage temperature, is first evident in the region of the large intestine, where the concentration of sulfide-producing bacteria is greatest. From the vent area, greening spreads upward, while the muscle tissue remains relatively free from microorganisms. The potential for greening is reduced by starving birds prior to slaughter, thus minimizing microbial growth in the intestine. It is generally thought that eviscerating carcasses outside the processing plant is likely to increase the risk of cross-contaminating other foods with fecal bacteria, and could be a hazard for foods that are ready to eat. Also, NYD carcasses cannot be properly examined by the inspectorate at the time of production and, theoretically, unfit carcasses could pass into the human food chain. These problems do not arise with carcasses that are kept in chill storage by the processor and ultimately eviscerated on the same premises.

20.5 FURTHER-PROCESSED PRODUCTS

Further processing converts carcass meat into a variety of value-added products that are popular convenience foods. It involves operations such as portioning, deboning, size reduction, tumbling, massaging, reforming, emulsifying, breading, battering, and marinading. The products may be cooked, cured, smoked, dehydrated, or canned, or appropriate combinations of these processes may be used.

Cutting of meat and the various steps involved in product manufacture increase the opportunities for microbial contamination, and it has been reported that counts can increase up to six-fold during plant cutting operations.[68] More centralized cutting and packaging of poultry, as occurs now in processing plants, has improved the control of microorganisms.[33,48] Ingredients of poultry products can also increase microbial contamination, especially spices, which sometimes contain large numbers of bacterial spores. In relation to manufactured products, use is made of the highly comminuted mechanically separated meat (MSM), which may serve as an ingredient or as a binder in reformed products. The process used to obtain MSM causes considerable cellular destruction, which releases nutrients and makes this material more prone to microbial growth and spoilage, as well as oxidative rancidity. Contamination of MSM is influenced by the type of raw material used, eg, whether or not it includes skin, which is more highly contaminated than muscle. Aerobic plate counts of 10^4–10^5 g^{-1} can be achieved, but counts are sometimes higher. MSM is normally held at 0° to 2°C for up to 48 hours or frozen before use.

Products that are sold as "ready to eat" receive an appropriate heat treatment that destroys most vegetative bacteria. The methods employed include water-bath pasteurization, boiling, baking, barbecuing, and frying. In some cases, eg, baked, barbecued, and fried items, the product is packaged after heat processing and therefore is susceptible to post-process contamination. In the UK, coated, flash-fried products that may appear to be cooked are, in fact, virtually raw and have caused food poisoning because of inadequate cooking by consumers.[119] This type of product needs clear labeling to indicate the further heating requirements.

Earlier studies on the safety of cooked poultry products were largely concerned with the control of *Salmonella* and *Staphylococcus aureus*, and it was shown that cooking to an internal temperature of 71.1°C eliminated any significant risk of human food poisoning from these organisms.[151] In inoculation studies on turkey roll,[20] the component pieces of meat were inoculated by dipping in a broth culture of the relatively heat-resistant *S. senftenberg* 775W to give a concentration of >106 cfu g^{-1} and pressed together to form rolls in a polyethylene casing. After cooking in an oven to an internal temperature of 65.6°C or heating at 62.8°C for 4 hours, the number of salmonellas was reduced to <0.3 g^{-1} or cm^{-2}. The heat treatment used to inactivate salmonellas would not be sufficient to destroy clostridial spores, including those of *Clostridium perfringens*. The heating process drives off oxygen, lowers the E_h of the meat, and provides a heat shock that can promote spore germination. Subsequent outgrowth must be controlled by prompt and efficient chilling of the cooked product. However, the chilling process may not prevent the growth of any psychrotrophic strains of *Clostridium botulinum*, especially in uncured and possibly smoked poultry products held in MAP, with a shelf life greater than 10 days. Manufacturers need to take account of this potential hazard in setting cooking temperatures and "use by" dates. To obtain a 6-$\log_{10}$ reduction in spores of psychrotrophic *C. botulinum*, a treatment equivalent to heating at 90°C for 10 minutes has been recommended.[116]

In relation to the risk of recontaminating cooked products prior to packaging, a study on foil-wrapped oven-roasted turkey rolls showed that post-cooking processing at two US factories had no significant effects on aerobic plate counts, but 8 of 28 rolls examined after packaging contained coagulase-positive staphylococci.[84] The organisms could have been acquired by cross-contamination from raw meat, contaminated equipment, or the hands of operatives. Under present conditions, where higher standards of handling hygiene are widely practiced, this problem should be avoidable.

Listeria monocytogenes is a common contaminant of raw poultry meat and may also be found in the further processing environment, where it is often associated with floors, drains, cleaning aids, processing equipment, and food contact surfaces. Heating foods to an internal temperature of 70°C for 2 minutes is recommended to ensure destruction of *L. monocytogenes*.[36,67] Occasional reports of unusually high heat resistance have been attributed to uneven heating of the product or the protective effects of fat or drying. Because human listeriosis can be a serious disease, with a significant level of mortality, contamination of ready-to-eat foods with *L. monocytogenes* is potentially hazardous and may lead to the recall of affected products from retail stores. Recalled products have included turkey frankfurters, chicken spread, and chicken salad.[32] The widespread occurrence of *L. monocytogenes* is a problem in relation to product contamination, even with rigorous application of HACCP principles, and low levels of contamination are likely to be present, ie, up to 100 g^{-1}, in a proportion of samples examined.[120] The organism survives well on poultry and grows better than on other kinds of meat, especially above pH 6.0.[38] It is also relatively resistant to curing agents, but may be adversely affected by some smoking treatments.[86]

Given the great diversity of further-processed poultry products, it is not surprising that there is no systematic information on the spoilage characteristics of these items during chill storage. In practice, the shelf life of cooked products is related to the severity of the cooking process, the extent of any post-processing contamination, the type of packaging used, and the time and temperature of storage. For unwrapped carcasses cooked in a circulating, moist-air oven at 85°C, with the meat temperature maintained for at least 50 minutes, only spore formers were detected, mainly *C. bifermentans* and *Bacillus subtilis*.[107] Storage at an abuse temperature of 16°C increased the numbers of vegetative organisms and off-odors were evident after 10 days. At 1° to 3°C, the carcasses showed no sign of spoilage after 4 weeks, and vegetative organisms did not increase in number.

Vacuum packaged, cured, and smoked chicken carcasses had a shelf life of 84 days at 1° to 5°C, following cooking to 70°C or 80°C, and 104 days at 1°C, when cooked to 99°C.[89] These conditions severely limited the growth of yeasts and molds, which otherwise would have spoiled the product within 8 days at 1°C. Another study, involving smoked chicken halves, showed that molds caused visible spoilage at 25°C and 15°C.[102] At these temperatures, spoilage was evident after 9 and 12 days, respectively.

Cooking usually destroys the psychrotrophic bacteria that cause spoilage of raw meat stored aerobically under chill conditions, although recontamination of the product may occur post-cooking. It has been reported that pseudomonads can spoil creamed or gravy products,[110] whereas, in products that are salted, as in kosher processing, the predominant spoilage organisms are salt-tolerant "*Moraxella*" spp.[59]

20.6 CONCLUDING REMARKS

In the developed world, poultry meat production is a highly intensive and efficient industry, which continues to expand in response to consumer demand. Despite its popularity, however, poultry meat is frequently contaminated with foodborne pathogens, such as *Salmonella* and *Campylobacter* spp., organisms that, in many countries, are major causes of human enteritis. While the ultimate safeguard is adequate cooking of the meat and good handling hygiene in the kitchen, the risk of illness occurring is inevitably influenced by flock infection and its control in the hatchery and on the farm, and by the use of hygienic practices in the processing plant. The transmission of foodborne pathogens in poultry production is significantly affected by the intensive nature of present systems for breeding, hatching, growing, and processing the birds. At present, there are no acceptable means of eliminating all foodborne pathogens from raw poultry, and control measures, if they are to be effective, must be applied uniformly at all stages in the production chain in order to minimize product contamination.

Although the situation on farms tends to favor the spread of any pathogens present, because large numbers of birds are reared together in close proximity, the controlled environmental conditions that are necessary for optimal poultry production can also be exploited to prevent flock infection. In this respect, the measures necessary to achieve high standards of biosecurity are well known, and control of *Salmonella*, at least, can be reinforced by the use of competitive exclusion treatment, vaccination, acid treatment of feed, etc, as appropriate. These control measures, either singly, or in combination, are usually applied at the upper end of the production pyramid, but much less so in relation to broiler flocks. The main reason for this is cost. In what is, essentially, a high volume, low profit margin industry, there are currently no financial rewards for producing meat that has only minimal levels of pathogens or, theoretically, is pathogen-free. Customers expect that the foods they purchase will be free from any hazard to human health, and they appear unwilling to pay any premium for foods produced in such a way that the risks are negligible.

At the processing plant, continuing developments in machinery and equipment have facilitated increased rates of carcass production, while maintaining product yield. Over the years, however, the process has shown little improvement in relation to hygiene control and, when improvements in individual items of equipment have been made, their use within the industry has been limited. Nevertheless, the importance of hygiene control in the processing plant is widely recognized because it ensures that the final product is of acceptable microbiological quality, with low numbers of any foodborne pathogens or spoilage organisms. The main problem with foodborne pathogens in processing is the considerable opportunity for cross-contamination, which cannot be prevented by the current GMP and HACCP programs alone. There is clearly a need to introduce a terminal decontamination treatment for carcasses that would provide a much-needed CCP and this is being explored. At present, it seems unlikely that the use of ionizing radiation would be widely accepted for the purpose and, in any case, there could be some logistical problems in treating the very large amounts of poultry meat being produced. In practice, any decontamination process must be effective, safe for both plant personnel and consumers, and not damaging to the environment if disposal of treatment material is involved. Suitable treatments are becoming available, but will need to be sanctioned more widely by regulatory bodies and their use encouraged.

Poultry meat is highly suitable as a raw material for product development and, with its light color and delicate flavor, can be transformed into a wide range of value-added convenience foods. With ready-to-eat products, there have been concerns over the possible presence and outgrowth of spores of psychrotrophic strains of *C. botulinum* and low rates of contamination with *L. monocytogenes*, which are currently unavoidable. Despite these problems, further-processed poultry products will continue to be developed and make a significant contribution to the high level of poultry meat consumption worldwide.

CHAPTER CONTENTS

21.1 Introduction
21.2 Chemical composition of fish and shellfish
21.3 Microbiology of freshly caught fish and shellfish
  21.3.1 Fish and shellfish from temperate waters
  21.3.2 Fish and shellfish from tropical waters
21.4 Microbiological hazards in fresh fish and shellfish
  21.4.1 Raw bivalve molluscs
  21.4.2 Fresh and packed fish and shellfish
21.5 Microbiological hazards in fish and shellfish products
  21.5.1 Lightly preserved seafood products
  21.5.2 Semipreserved seafood products
  21.5.3 Heat-treated seafood products
21.6 Concluding remarks
References

21.1 INTRODUCTION

Fish and shellfish constitute a very important part of the diet in many parts of the world and with the increasing world population, effective utilization of all food resources is of major importance. While "milk," "meat," and "egg" may each denote a relatively well-defined group of raw material, "fish" covers an enormous range of species; currently approximately 20,000 different species have been identified. These are caught or harvested over a wide range of conditions, from the cold waters of Greenland to the warm waters of Southeast Asia, from freshwater lakes to oceans with 3% to 4% salt. In terms of composition of the raw material, fish range from white fleshed low-fat fish with large regular fillets to small, fatty pelagic fish species with many bones in the fillet. As opposed to many other food raw materials, fish are mainly harvested from a wild population and only a small, but increasing, fraction is cultured in mari- or aquaculture. Despite these variations, there are many general features in the microbiology of the fish and fish products.

Fish and shellfish are processed using almost every known food preservation technique; however, the trend in most parts of the world is toward more fresh and less preserved products (Table 21-1).

Most studies of the microbiology of fish and fish products have been carried out using a few selected fish species, like cod and plaice, from temperate, marine waters. During the last five years the total production of fish and shellfish has been just under 100 million tonnes.[77,79] In the same period, the so-called developing countries have surpassed the developed countries in terms of amount of fish supplied, and approximately 60% now comes from these countries.[77] This emphasizes the need for an understanding of the microbiology of fish caught or harvested in warmer, tropical waters, and utilized as raw materials for further processing.

In contrast to the decline in wild fish catches, the amount of reared fish and shellfish increased from 7 million tonnes in 1984 to 13.9 million tonnes in 1992.[48] While the amount of wild fish that can be used for human consumption is expected to remain at 60 million tonnes per year, it is estimated that the amount of reared fish will increase to 25 million tonnes in year 2000.[48] Farming of fish has obvious advantages in terms of ability to control chemical composition of the fillet, growth rate, harvesting time, etc. In microbiological terms, farming of fish poses a special problem partly resulting from the usage of antibiotics which, as in any intensive farming, may cause development of antibiotic-resistant bacteria that, via the food, can be transferred to the consumer.

The growth and metabolism of microorganisms give rise to two hazards in food (fish) products, disease (infection, intoxication), and/or spoilage.

Statistics of foodborne diseases are generally quite inaccurate as only a fraction of diseases are reported and only in some (of the reported) cases are the etiological agents identified. Statistics from the United States (US), Canada, and the Netherlands show that seafood is implicated in 8% to 10% of the outbreaks of foodborne disease[121] and in some areas, seafood products are the most commonly implicated vehicles.[262] Thus, in Korea and Japan fish and other seafood products were the most commonly implicated vehicles of foodborne disease accounting for 32% and 22%, respectively, of the outbreaks.[163] However, in several of the reported outbreaks only few people were affected,[30] and seafood only accounted for 3.6% of the cases of foodborne illness in the US from 1978 to 1987.[174] In contrast, the largest foodborne disease outbreak ever recorded was caused by hepatitis A in China where 290,000 people were infected by undercooked shellfish.[258] The causes of disease vary depending on the raw material. Marine toxins (eg, ciguatera) and scombroid toxin are the most important agents of disease transmitted by fresh and frozen fish[121] (see Chapter 54) whereas viruses and marine vibrios are implicated in 38% of diseases transmitted by shellfish.[121,174,223] The etiological agents responsible for health hazards of seafoods are listed in Tables 21-2 and 21-3. Bacteria indigenous to the aquatic environment are usually present on the raw material, although mostly in low numbers. Apart from some vibrios that may be found in high numbers (see below), prevention of disease caused by indigenous organisms relies on prevention of bacterial growth. Nonindigenous bacteria are either part of the general environment (eg, *Listeria monocytogenes* and *Clostridium botulinum* type A and B) and as such often present in water, or are found on seafood as a result of human (often fecal) contamination. For a thorough discussion of all the agents, including parasites, and their importance in fish products, the reader is referred to Huss[121] and Chapters 38 through 54 in Vol. II of this book.

It has been estimated that 25% of all fresh food spoil because of microbial action,[82] and the Food and Agricultural Organization (FAO) estimates that post-harvest losses in the fishery sector are in the same range. While these losses, particularly in tropical countries, are to some extent due to insect infestation, microbial spoilage is of major importance.

21.2 CHEMICAL COMPOSITION OF FISH AND SHELLFISH

The chemical composition of fish varies depending on the species, age, environment, sexual cycle,

Table 21-2 Bacterial Health Hazards Associated with Fish and Shellfish Products

Indigenous		*Nonindigenous*

etc, but consists of approximately 20% protein, 1% to 2% nonprotein dry matter, the remaining 78% being a combination of water and lipid. The proportion of lipid and water varies dramatically depending on species and season. This rarely influences the microbiology of the product but affects quality and is of major technological importance due to problems caused by oxidation of the polyunsaturated fatty acids of fish lipids. A major difference from the mammalian muscle is the very low level of carbohydrate because fish do not, as do warm-blooded animals, accumulate glycogen. This has important consequences for the microbiology of fish as the pH *postmortem* is >6.0 in most fresh fish, which is higher than in mammalian muscle (Figure 21-1). Bivalve molluscan shellfish (clams, oysters) differ from the other aquatic animals because they are able to accumulate glycogen (0.5% to 6.8% depending on spawning cycle) in the muscle.[44]

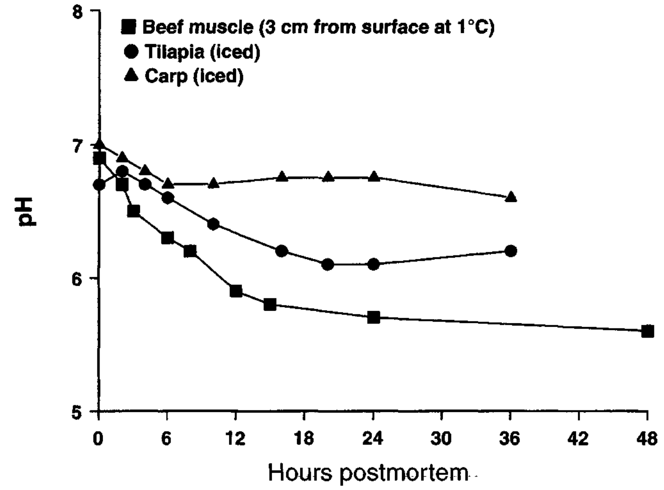

Figure 21-1 pH Changes *Postmortem* of Beef Muscle (*M. longissimus dorsi*), Tilapia (*Oreochromis aureus/niloticus* hybrid), and Carp (*Cyprinus carpio*). *Source:* Data from C.A. The most important chemical fraction in relation to the microbiology of fish products is the nonprotein nitrogen (NPN) fraction. This consists of low molecular weight, water-soluble, nitrogen-containing compounds including amino acids, nucleotides, and trimethylamine oxide (Table 21-4). The NPN fraction is the major bacterial growth substrate. In a classical experiment, Lerke et al.[168] separated fish juice into a high molecular weight fraction (proteins) and low molecular weight fraction (NPN compounds) and showed that while spoilage bacteria grew well in the former, spoilage off-odors were only, and to the same extent as in fresh fish, produced in the NPN-containing fraction. Differences in the composition of the NPN fraction influence both potential bacterial health hazards and bacterial spoilage, as discussed below.

Trimethylamine oxide (TMAO) is one of the most important components of the fish muscle. It is an

odorless compound typical of marine fish species,[108] particularly the gadoid fish, but contrary to earlier beliefs it also occurs in high concentrations in some freshwater fish species, eg, tilapia and Nile perch.[13,102,213] TMAO can be used by several bacteria as a terminal electron acceptor in anaerobic respiration. Reduced TMAO, trimethylamine (TMA), smells of old fish and is perhaps one of the most typical components of the odor profile of spoiling fish. For a number of fish species, TMA is used as a chemical indicator of spoilage.[203] The reduction potential of TMAO/TMA is +120 to +140 mV in nutrient broth at pH 7.0.[35] The redox potential in a fish fillet is positive (up to +100 to +300 mV probably depending on pH) as long as TMAO is present whereas E_h drops dramatically to negative values (to –300 mV) once TMAO is reduced.[124] The positive redox potential of fish may influence the microbiology, such as the growth and metabolism of anaerobic organisms. *C. botulinum* type E grows and produces toxin in fresh fish irrespective of the presence of TMAO.[128] Using O_2 to adjust Eh, it was shown that at 3.25% NaCl, the organism was much more sensitive to changes in Eh,[177] and the presence of TMAO has been suggested as an extra hurdle against growth of *C. botulinum* in salted fish.[129] Spoilage of sugar-salted herring by strict anaerobic organisms is only seen at low Eh, that is, if TMAO or any other oxidizing compound (like nitrate) is not present.[154]

Elasmobranches discharge nitrogen by accumulation of urea, which is a protein-denaturing agent. TMAO counteracts the protein-denaturing effect of urea,[275] and this is believed to be the reason for the high TMAO concentration of elasmobranches (Table 21-4). While TMAO is considered nontoxic to mammals, very high concentrations of TMA may, in fact, be toxic. Greenland sledge dogs that ingest large amounts of raw shark meat suffer from symptoms of TMA poisoning. It has been suggested that this is due to the reduction of TMAO by the dog intestinal microflora.[14]

The amino acid histidine is present in free form in herring and in scombroid fish species such as tuna and mackerel. Some bacteria, particularly among the Enterobacteriaceae, are able to decarboxylate this amino acid resulting in the formation of histamine. Histamine together with other biogenic amines (tyramine, spermine) may be implicated in a hypersensitive reaction in humans known as scombroid poisoning. Histamine formation is mainly a problem caused by temperature abuse of raw fish,[251] but has also been reported to take place in fish stored at low temperatures.[3,271] For further information, see below and Chapter 54.

The pool of free amino acids provides important substrates for bacterial growth.[222] The decomposition of the sulfur-containing amino acids cysteine and methionine is important in spoilage as it results in formation of hydrogen sulfide and methyl mercaptan, respectively.[109,110] The very high content of certain amino acids in crustaceans (Table 21-4) contributes to their typical, sweet flavor.

Some of the properties of fish muscle that influence the microbiology of fish and shellfish are summarized in Table 21-5.

21.3 MICROBIOLOGY OF FRESHLY CAUGHT FISH AND SHELLFISH

Microorganisms are found on all the outer surfaces (skin and gills) and in the intestines of live and newly caught fish. The number of culturable organisms varies with a normal range of 10^2–10^6 cfu cm^{-2} on the skin surface (Tables 21-8 and 21-9),[173] and the

Table 21-5 Properties of Muscle from Newly Caught and Spoiled Fish Compared with Those of Muscle from Fresh Beef

	Value/Characteristic		
Parameter	*Fresh Fish*	*Spoiled Fish*	*Fresh Beef*
Water activity	0.98	0.98	0.98
Redox potential	positive (+100 to > +300 mV)	negative (–200 to –400 mV)	negative
pH	high (6–7)[a]	6.5–7.5	low (5.4–5.5)
Nutrients	rich in nonprotein nitrogen free amino acids (75–3000 mg 100 g^{-1}) TMAO (0–350 mg 100 g^{-1}) nucleotides	—	rich in nonprotein nitrogen free amino acids (350 mg 100 g^{-1}) no TMAO
Structure	low in carbohydrate (<0.5%) skin/slime with some protective function	— —	high in carbohydrate (1% to 2%)

[a] Some fish species (halibut, tuna) may have a *postmortem* pH of approximately 5.5.

gills and the intestines both contain between 10^3 and 10^9 cfu g^{-1}.[239] As in other environments, not all the microorganisms may be culturable, thus Bernadsky and Rosenberg[25] found 4×10^8 bacteria cm^{-2} on cornetfish were stainable by the DNA stain DAPI (4,6-diamidino-2-phenylindole) or could be visualized by scanning electron microscopy but only 2×10^4 bacteria cm^{-2} were culturable on marine agar incubated at 25°C for 3 days.

The bacterial flora on newly caught fish depends on the environment in which it is caught rather than on the fish species.[241] Fish caught in very cold, clean waters carry lower numbers than fish caught in warm waters.

21.3.1 Fish and Shellfish from Temperate Waters

Wild Fish and Shellfish

The microflora on temperate water fish and shellfish is dominated by psychrotrophic or psychrophilic, Gram-negative, rod-shaped bacteria belonging to the genera *Pseudomonas*, *Moraxella*, *Acinetobacter*, *Alkaligenes*, *Shewanella*, and *Flavobacterium*. Members of the *Vibrionaceae* (*Vibrio* spp. and *Photobacterium* spp.) and the *Aeromonadaceae* (*Aeromonas* spp.) are also common aquatic bacteria and typical of the fish flora (Table 21-6). *Aeromonas* spp. are typical of freshwater fish, whereas a number of bacteria require sodium for growth and are thus typical of marine waters. These include *Vibrio*, *Photobacterium*, and *Shewanella*. *Shewanella putrefaciens* is characterized as sodium requiring, but strains of *S. putrefaciens* can also be isolated from freshwater environments.[62,103,248] Gram-positive organisms such as *Bacillus*, *Micrococcus*, *Clostridium*, and *Corynebacterium* can also be found in varying proportions (Table 21-6). Lactic acid bacteria are seldom part of the dominant flora, but are present at levels of $10–10^3$ g^{-1}.[151,235]

Table 21-6 Bacterial Flora on Newly Caught Fish and Shellfish from Tropical and Temperate Marine and Fresh Waters

	Incidence (%)			
	Temperate		*Tropical*	
Species	*Marine*	*Fresh*	*Marine*	*Fresh*
Gram-negative				
Pseudomonas	0–70	0–22	0–53	0–16

Enterobacteriaceae[c]		0–18	0–10	
Chromobacterium			0–20	
Gram-positive				
Micrococcus	0–53	0–10	0–60	0–30
Staphylococcus			0–41	0–18
Bacillus[d]	0–24		0–42	0–5
Coryneforms	0–10	0–12	0–55	0–5
Lactic acid bacteria			0–3	

[a] *Achromobacter* denotes Gram-negative, nonfermentative rods. Probably covers strains now identified as *Acinetobacter* and *Moraxella*. Includes also *Shewanella putrefaciens*, which is found in low numbers on newly caught fish.

[b] Includes also *Photobacterium phosphoreum*.

[c] In clean waters mainly psychrotrophic strains (eg, *Serratia liquefaciens* or *Hafnia alvei*).

[d] Clostridia may be isolated in low numbers.

Data from 6, 19, 31, 47, 75, 89, 103, 116, 157, 173, 216, 241, 253, 276.

Several types of *C. botulinum* are found in the aquatic environment. However, the nonproteolytic type E, which is psychrotrophic, is believed to be truly indigenous and occurs especially in temperate and subarctic zones.[119] *C. botulinum* is found in most sediments and on fish from different parts of the world. Quantitative data are scarce; however, numbers of spores in sediments are usually less than 100 g^{-1} although higher values have been reported in the Great Lakes in the US and in the Sound in Scandinavia.[63] It is hypothesized that the organism proliferates in dead fish and aquatic mammals[120] and the increasing environmental problems in the oceans, anoxic conditions, and mass fish mortality may have increased the numbers of *C. botulinum* in sediments and wild fish.

The proportions of the different bacterial groups vary (Table 21-6) and comparing the exact numbers is difficult, partly due to the change in classification of several of the organisms. The organisms that in earlier publications were identified as *Achromobacter* spp. include the following: (1) nonmotile rods, which are now either *Moraxella* or *Acinetobacter*; (2) motile rods now assigned to *Alcaligenes*; and (3) certain nonfluorescent rods now identified as *Pseudomonas* spp. or *Alteromonas* spp.[115]

Aeromonas spp. proliferate in the intestinal tract of freshwater fish[252] where they may occur in numbers of $10^5–10^7$ cfu g^{-1} and up to 10^7 cfu g^{-1} of vibrio-like organisms can be present in the intestinal tract of cod[161] and turbot.[274] *Photobacterium phosphoreum*, which can be isolated from the surface of fish, can also be isolated in high numbers ($10^7–10^8$ cfu g^{-1}) from the intestinal tract of some marine fish species.[192,269]

Farmed Fish and Shellfish

The natural bacterial flora on farmed fish and shellfish from temperate waters is similar to the microflora of wild fish.[248] However, as the microflora on fish is a reflection of the environment, fish reared in ponds or in shallow near-coast waters are closer to man (and his wastage) than are the wild fish, and this may cause a higher frequency of contamination with bacteria nonindigenous to water. Thus *Listeria monocytogenes* was not isolated from unpolluted ocean waters and spring water, but the organism could frequently be isolated from surface waters (up to 62% positive samples) and polluted seawater (up to 33% positive samples).[130] It is therefore not surprising that low levels of *L. monocytogenes* are found on raw fish, eg, salmon, and on products that do not receive a listericidal treatment, eg, cold-smoked salmon.[21,130] Although most investigators have presented qualitative data, Huang and Leung[117] reported low counts of *Listeria* spp. (2–20 g^{-1}) on caged channel catfish, and it is likely that in general, the numbers of *L. monocytogenes* on raw fish are very low. A few investigations state numbers on fish products like cold-smoked salmon and these are discussed in Section 21.5.

The highest ever recorded number of *C. botulinum* type E spores on fish (5.3 g^{-1}) was found in Danish farmed trout.[127] As the organism proliferates in dead fish and aquatic mammals, it was suggested that the use of wet fish as aquaculture feed, as well as poor hygienic measures, was the reason for this high number. During recent years, the use of wet feed has been prohibited.

As fish and shellfish become farmed animals, diseases become a major problem. The use of antibiotics, particularly of tetracyclines, has been very common, thus 50,000 kg of antibiotics were used in 1987 in Norway for the production of 4,000 tonnes of salmon. Fortunately, the development of vaccines have caused a decrease in the amount of antibiotics used, and in 1993 only 6,000 kg of antibiotics were used in Norway for the rearing of 170,000 tonnes of salmon.[11] A lot of effort is currently being put into development of vaccines and probiotic treatments; however, the usage of antibiotics has been, and continues to be, very widespread. This raises concerns about the development of antibiotic resistance.[9] The development of resistance in the pathogenic flora of fish causes further problems for the fish processor, whereas the consumer and health authorities are more alarmed by the possible development of resistance in human pathogens transferred from the microflora of the fish or by the general spread of antibiotic resistance in the aquatic microflora. Several studies show that waste waters from hospitals, farms, and communities increase the antibiotic resistance of enteric organisms found in the water,[107,113] and it has been demonstrated that usage of oxolinic acid and oxytetracycline increased the level of antibiotic resistance in the normal fish microflora.[60,248] Thus, 29% and 27% of 202 isolates from fish farms (where antibiotics were used) were resistant to oxytetracycline and oxolinic acid, respectively, whereas similar values for 94 isolates from an unpolluted stream were, respectively, 6% and 16%.[248]

21.3.2 Fish and Shellfish from Tropical Waters

Wild Fish and Shellfish

The bacterial load on fish caught in clean tropical waters does not differ from counts on temperate fish species (10^2–10^6 cfu g^{-1}, Table 21-8, Table 21-9), however, very high numbers of Enterobacteriaceae (up to 10^7 cfu g^{-1}) can be found on fish caught in polluted warm waters.[97] Despite the warm water, a large proportion (20% to 50%) of the microflora on tropical fish is capable of growth at chill temperatures.[102,197,254]

Shewan[241] concluded that *Bacillus* and *Micrococcus* spp. dominate on fish from tropical waters. Some studies do report high incidences (30% to 50%) of these species[18,253] and tropical waters can contain quite a high proportion (10% to 30%) of Gram-positive organisms.[138] Often, however, the microflora on tropical fish species is very similar to the flora on temperate species (Table 21-6),[6,103,159,172,254] and several authors conclude, as Liston,[173] that the microflora on tropical fish often includes a slightly higher load of Gram-positives and enteric bacteria but otherwise is similar to the flora on temperate water fish.

Several microorganisms pathogenic to humans occur naturally in warm waters; thus most mesophilic vibrios, *Vibrio parahaemolyticus, V. vulnificus*, and *V. cholerae* are found in tropical marine and estuarine waters.[174,223,224] *V. parahaemolyticus* could be isolated year round in tropical Indonesian waters with the lowest incidence (33% positive samples) in December and February and the highest (all samples positive) in July, and the organism was also often isolated from seafood (44% to 100% positive) from the Jakarta area.[191] *V. parahaemolyticus* occurs frequently in the warmer waters around the US with a mean density of 10–20 per 100 ml water.[61] Interestingly, the organism is concentrated in filter-feeding animals, and numbers in oysters are typically 100-

fold higher (up to 5 $\times 10^4$ 100 g^{-1}) than in the surrounding waters.[61] Despite its primary association with the marine environment, *V. parahaemolyticus* can also be isolated from freshwater fish from warm waters. Sakar et al.[234] found an MPN of up to 0.9 g^{-1} in fish from Indian fresh waters and up 90 g^{-1} on plankton and 25% to 30% of newly caught fish were positive for *V. parahaemolyticus*.

Vibrio vulnificus is a mesophilic organism occurring in estuaries in the warm summer months with water temperatures of ≥15°C[205] in which reported disease outbreaks peak.[223] Numbers in the Gulf of Maine ranged from 10^3 100 g^{-1} oyster or ml^{-1} water in July and August (water temperature ~20°C) to below the detection limit in January and February (water temperature <10°C).[205] DePaola et al.,[59] however, found 10^3–10^9 100 g^{-1} or ml^{-1} in fish intestines, oysters, and water from Mobile Bay and Mississippi Sound with the highest numbers found in intestines of bottom fish that fed on molluscs. Such fish and molluscs are obviously a great risk unless cooked or prepared in other ways that eliminate the organisms.

Farmed Fish and Shellfish

As in temperate waters, the microflora on fish and shellfish reared in tropical waters does not differ from the microflora on wild fish.[31,277] However, in some countries in Southeast Asia the fish ponds are enriched with human or animal excreta[273]; for example, chicken manure is used as an organic fertilizer in shrimp farming in Thailand.[57] This obviously raises concern about the level of fecal contamination and several studies have been conducted assessing the prevalence of *Salmonella* and other enteric bacteria in tropical shrimp farming. These organisms do not survive in cold, nutrient-deprived waters, but *Salmonella* and *Esherichia coli* are able to persist and even grow in warm waters.[86,141] Both brackish-water ponds and shrimp from a major producer in Southeast Asia were inherently contaminated with *Salmonella* spp., which were present in 16% of prawns and 22% of mud/water samples from ponds.[217] In contrast *Salmonella* was not isolated from any of 158 samples of water, sediment, shrimp, feed, or chicken manure taken from a Thai shrimp producer[57] and *Salmonella* or fecal coliforms were not detected in Indian cultured prawns.[254]

Several countries require that *Salmonella* are absent from raw, frozen prawns, based on the fact that it is not of marine origin and therefore not a natural part of the microflora. Findings like those cited above show that occurrence of *Salmonella* or *E. coli* cannot be attributed exclusively to poor sanitation or standards of hygiene during processing but are due to conditions during production.[217] Standards, precautions, and preventive measures therefore have to be evaluated according to the production area.

Marine vibrios are found on shellfish and fish reared in tropical waters. Thus *V. cholerae*, all of which were the non-O1 serogroup, were present in 1.5% of prawns and 3.1% of mud/water samples from major aquaculture areas in Southeast Asia.[217] *V. cholerae* non-O1 was isolated from 33% of water, sediment, and shrimp samples from Thai shrimp farms, whereas 2 out of 107 samples were positive for *V. cholerae* O1[57] and *V. cholerae* was detected in Indian cultured shrimp.[196] As in wild fish the incidence of both *V. parahaemolyticus* and *V. vulnificus* was high; 100% and 67% positive samples, respectively.[196]

The problems relating to development and spread of antibiotic resistance are also a concern in tropical aqua- and mariculture; 3 out of 5 *Plesiomonas shigelloides* strains, 4 out of 12 *Salmonella* strains, and 10 out of 13 *Aeromonas hydrophila* isolated from tropical fish farms were resistant to tetracyclines and of a total of 118 isolates, 6% to 75% were resistant to a range of eight different antibiotics.[266]

21.4 MICROBOLOGICAL HAZARDS IN FRESH FISH AND SHELLFISH

The flesh of healthy live fish is generally thought to be sterile as the immune system of the fish prevents the bacteria from growing in the flesh. A notable exception is the muscle of live oysters in which high numbers of *V. vulnificus* are found.[257] When the fish dies, the immune system no longer functions and any bacteria present are able to proliferate freely. The microflora on a fish product will be a function of the natural, indigenous flora (see above) and the microflora typical of the processing environment. The preservation conditions of a given product will typically allow for growth of only a fraction of the microflora and the sections below describe how microorganisms survive, grow, and interact in different fish and shellfish products.

The ability of pathogenic and spoilage microorganisms to grow under different combinations of preservative factors has been studied for many years and during the last decade mathematical quantification of bacterial growth has been used in numerous predictive models.[185] Predictive models, or rather the understanding of microbial ecology on which they are based, is an essential tool in any quality assurance scheme.[187] To date, models evaluate the effect of chemical and physical factors on growth of bacteria and do not take into account interactions between microorganisms in food products.[100]

Spoilage is defined in this context as sensory changes that render the product unacceptable for human consumption. While this occurs for some products as a result of chemical changes, eg, lipid oxidation or bleaching of pigment, the focus of this chapter will be on rejection due to off-odors and off-flavors that are caused by bacterial metabolism. Spoilage of fish cannot be correlated with the total number of mesophilic or psychrotrophic bacteria that develop[38,131] but is often caused by the activities of a minor part of the microflora. An understanding of the specific organisms that are important for spoilage will allow development of better preservation methods and the use of predictive models for determination of shelf life.[51,96,146]

A clear distinction should be made between the terms *spoilage flora* and *spoilage organisms (bacteria)* because the first describes merely the bacteria present on the fish when it spoils, whereas the latter is the specific group that produces the off-odors and off-flavors associated with spoilage. In order to determine which bacteria are the cause of spoilage of fish, the sensory, microbiological, and chemical changes during storage must be measured and the concentration of chemical compound(s) that correlates with spoilage (the chemical spoilage indicator) should be determined. Pure and mixed cultures of bacteria isolated at the time of spoilage are screened in sterile fish substrates for their *spoilage potential,* ie, their ability to produce sensory (off-odors) and chemical changes typical of the spoiled fish.[36,101,111] Selected strains are tested to evaluate their *spoilage activity,* ie, the relation between their growth rate and their *qualitative* and *quantitative* production of off-odors.[52,95] Spoilage potential and activity can be assessed in substrates such as sterile, raw fish juice,[167] heat-sterilized fish juice,[37,52,101] or on sterile muscle blocks.[111] The latter is the most complicated but is most comparable with whole fish.

21.4.1 Raw Bivalve Molluscs

Molluscs are filter-feeding organisms, and many agents in the surrounding waters are concentrated in the animal. They are grown and harvested in shallow, near-shore estuarine waters and are therefore very likely to harbor high concentrations of pathogenic organisms. As they often are eaten raw (with the intestinal tract) or after a very mild heat treatment they constitute a serious health risk.

Several regulations contain bacteriological specifications for quality of waters used for culturing of molluscs. In the US specifications include a limiting MPN count of up to 14 fecal coliform bacteria 100 ml^{-1} water, with no more than 10% of the samples with an MPN count up to 43 fecal coliform bacteria 100 ml^{-1}.[81] However, the value of these indicators is limited for several reasons. First, there is no direct relationship between the microbial content of the filter-feeding bivalve and that of the aquatic environment. Second, the level of indicators does not correlate with the occurrence of human pathogens, eg, *Salmonella,* in the animal. For instance, Martinez-Manzanares et al.[183] found *Salmonella* in 41% of 29 shellfish samples from water with $<10^2$ fecal coliforms 100 ml^{-1} whereas only 29% of 22 shellfish samples from waters with $>10^2$ fecal coliforms 100 ml^{-1} contained *Salmonella.* Such discrepancies may be explained by the investigations showing that *Salmonella* can persist longer in estuarine waters than *E. coli,*[218] obviously raising the question of the suitability of fecal coliforms, for example, as indicator organisms in this environment.[148]

The European Union (EU) has no microbiological standards for waters in which bivalve molluscs are grown but has placed standards on shellfish for direct consumption (see below). The regulation also contains maximum limits for various marine toxins (see Chapter 54) and requires that the growing area is surveyed for toxic phytoplankton.[68]

Molluscs may, at least partly, be cleansed of microbiological contaminants by placing them in clean water in which they actively feed. The relaying procedure involves moving the molluscs to approved shellfish growing waters, whereas depuration is the procedure in which the animals are brought into tanks with clean water of appropriate salinity and temperature. Several countries including Australia, New Zealand, the United Kingdom (UK), Spain, Italy, France, Denmark, Canada, and Turkey require that bivalve molluscs be depurated.[225] While depuration may remove enteric pathogens, neither biotoxins nor chemicals are removed by these procedures and some viruses (eg, hepatitis A) and vibrios persist despite depuration.[135,209,221] Up to 18% to 40% of hepatitis A virus has been found after 5 days of depuration.[135,221] While 10^2–10^3 *E. coli* g^{-1} clam were reduced more than 100-fold by depuration for 24 hours, a similar level of *Vibrio parahaemolyticus* remained constant for 24 hours and decreased to approximately 10% in 3 days.[105] Similar levels of *V. parahaemolyticus* were found in unpurified and depurated (24 hours) Sydney Rock oysters.[74]

Health Hazards

Raw bivalve molluscs (oysters, clams) are very frequently implicated in foodborne disease,[223] thus the majority of all seafood-related diseases in the US are related to consumption of bivalve molluscs.[44] Despite strict regulations for the water quality in the areas in which molluscs are harvested (see above) and various depuration regimes, viral diseases (hepatitis) and gastroenteritis (*V. parahaemolyticus* gastroenteritis), cholera, and recently cases of *V. vulnificus* infection are caused by molluscs.[44] As mentioned in Section 21.1, the largest reported outbreak of foodborne disease was hepatitis A infection involving 290,000 people in China who had consumed undercooked mussels.[258] Until the 1950s, typhoid was frequently transmitted by molluscan shellfish[220,223] but has largely disappeared in the US probably because of fewer cases of waste discharge and improved sewage treatment.[29] A large number (70%) of the outbreaks of disease caused by molluscs in the US (1970–1984) were of unknown etiology.[121]

Hepatitis A and Norwalk viruses are major causes of disease associated with molluscan shellfish. Viruses are able to persist in bivalve molluscs for a longer time than fecal coliform bacteria and these bacteria are therefore not adequate indicators of virus contamination of bivalve molluscs.[220,261] Viruses are heat sensitive and some countries, eg, the UK, require a minimum heat treatment of 90°C for 1 minute for the treatment of cockles from some sources. However, most shellfish are eaten raw or after only a light heat treatment (steaming), which will not affect the viruses.

Several of the health hazards associated with bivalve molluscs are caused by vibrios that are indigenous to the marine environment and their occurrence obviously does not correlate with any of the commonly used indicator organisms.[175] Much focus has recently been on *V. vulnificus*, which causes wound infections or gastroenteritis. In people with liver disease, the mortality rate exceeds 50%. Several attempts have been made, particularly in the US, to devise procedures that would control this organism without altering the sensory charateristics of the product. As *V. vulnificus* is sensitive to various preservative factors, combinations of chilling, lowering pH, mild heating, or irradiation have been suggested.[8,45] However, as the infectious dose is low, this is unlikely to guarantee safety.

Although cholera is mainly a disease associated with contaminated water supplies, *V. cholerae* may also be transmitted by seafood.[29,223] The organism can persist in molluscs and is not spontaneously cleared during depuration.[209] *V. cholerae* is able to survive for long periods in both chilled and frozen products (see Chapter 48). However, because it is heat sensitive, it is mainly a problem of raw foods, particularly bivalves, or if poor hygiene allows for cross-contamination.

Some cases of gastroenteritis caused by cooked oysters have been linked to *Plesiomonas shigelloides*.[230] Although the organism has been isolated from patients with diarrhea, it is not a proven cause of gastroenteritis.[224]

Because the bacteriological quality of bivalve molluscs cannot be predicted from the water quality, the legislative authorities in some countries use end-product testing. The US specifies a limit of <230 MPN fecal coliform per 100 g meat and an aerobic plate count not exceeding 5×10^5 cfu g^{-1}.[81] Similar limits for fecal coliforms are set by the EU that also requires the absence of *Salmonella* in 25 g and set limits for biotoxins.[68] However, unless the bivalves are tested for all potential pathogens, there is no way of guaranteeing their safety and "if people would stop eating uncooked molluscan shellfish and certain types of tropical reef fish, more than 60% of all presently reported seafood-originated illness would not occur."[174]

Spoilage

As most bivalve molluscs are eaten raw, the animal is often alive until just before consumption and the immune system of the organism protects it against spoilage. Chilled molluscs meat removed from the shell ("shucked") has a short shelf life of 5 to 10 days at 1° to 3°C. Little is known about the microbiology during storage, and some authors have suggested that a spoilage dominated by fermentative organisms (lactobacilli, streptococci) takes place.[44] Because of the glycogen content, the pH of the molluscs drops more than that of crustaceans and fish, and the growth of fermentative organisms is therefore likely. However, Kator and Fisher[149] found that although the internal pH of sea scallop dropped to 5.5, the pH on the outer surface remained above 6.0 and increased as storage progressed. The aerobic psychrotrophic count increased from an initial 10^4 cm^{-2} to 10^9 cm^{-2} after 15 days at 2°C. Spoilage was caused by "yellowing" attributed to growth of *Pseudomonas* spp., indicating that the spoilage of chilled molluscs is caused by the same organisms that spoil chilled fish and shellfish (see below).

21.4.2 Fresh and Packed Fish and Shellfish

Fish and shellfish that are distributed fresh receive only very limited processing. The fish or shellfish are caught and in many areas chilled. In some areas of the world, some fish species are eviscerated on board the boats, and in North Europe gutting of white, lean species is compulsory. For instance, cod will deteriorate faster if left ungutted as discoloration and off-odors appear at the belly area after a few days of iced storage.[122] In other fish, such as South American hake, gutting has no influence on quality.[122] Chilling of fish and shellfish is usually done by storage in crushed ice or by covering in chilled seawater (a mixture of ice and seawater). Both procedures will, if done correctly, chill the fish to –1.5° to 1°C. Further processing often involves filleting and skinning before packing and distribution. Fillets (or whole fish) are distributed aerobically or packed under vacuum or in modified atmosphere. The effects of different packing methods on health hazards and spoilage are discussed below.

Health Hazards

Fresh fish of good quality is very unlikely to be the cause of disease if it is not temperature abused and if heated before consumption. The majority of public health hazards related to fresh and packed fish are caused by scombroid toxin and ciguatera toxin (see Chapter 54). Thus, 31% of diseases transmitted by fish in the US from 1970 to 1984 were caused by ciguatera toxin, and 33% were caused by scombroid toxin.[121] Most bacterial disease-causing agents will grow poorly in competition with the natural Gram-negative microflora and, in general, the products will spoil before hazardous levels of organisms or toxin(s) are reached.

Clostridium botulinum. Many studies have investigated the ability of psychrotrophic *C. botulinum*, particularly type E, to grow and produce toxin in fresh fish. Oxygen is inhibitory to *C. botulinum*[71,129] and a review of published experiments showed that fish stored aerobically at chill temperatures (0° to 12°C) spoil before becoming toxic.[214] At higher temperatures (>20°C) spoilage and toxin production in aerobically stored fish sometimes coincided.[214] Concerns have been raised about growth of psychrotrophic nonproteolytic *C. botulinum* in fish packed under vacuum or in modified atmosphere.[80,88] Although the elimination of oxygen during vacuum packing may enhance growth and toxin production by *C. botulinum*,[129] several studies have concluded that only at abuse temperatures will vacuum packed fresh fish become toxic at or before spoilage.[71,215]

Vacuum packed fresh blue crab, tilapia, rainbow trout, flounder, cod, and whiting inoculated with spores of *C. botulinum* type E all spoiled at 4° to 10°C before toxin could be detected (Table 21-7).[88,106,210,215] Lilly and Kautter[171] tested 1,074 portions of commercially packed fresh fish and none became toxic before spoilage. Variable data have been obtained in experiments evaluating whether fish packed under CO_2 become toxic before spoilage. When stored at high temperatures, fish packed in modified atmospheres may become toxic (if inoculated with *C. botulinum* type E) before or at time of sensory spoilage.[214] Eklund[71] found that fresh salmon inoculated with 100 spores of *C. botulinum* type E 100 g^{-1} and stored under 60% or 90% CO_2 at 10°C became toxic within 10 days, and before spoilage. At lower temperatures (0° to 8°C) most studies have found that fresh fish packed in modified atmosphere spoil before containing botulinum toxin (Table 21-7). Eklund[71] similarly concluded that packed (vacuum or modified atmosphere) fresh fish only presents a potential botulinum problem if temperature abused. In contrast to these conclusions, cod inoculated with 50 spores g^{-1}, packed under 100% CO_2 and stored at 4° or 8°C became toxic before being rejected (Table 21-7).[210] Three of 1,016 noninoculated fish packed in modified atmosphere and stored at 8°C were toxic before spoilage was evident. The shelf lives of cod reported[210] are, however, in our opinion and experience unrealistic and shelf life of MAP cod even at 0° to 2°C is normally below 21 days due to spoilage by CO_2-resistant, TMA-producing bacteria.[54] Challenge trials are usually done with inoculated spores at levels of 30–80 g^{-1},[214] whereas the natural contamination is much lower, typically 1–200 kg^{-1},[64] partly explaining why packed fresh fish has never been implicated in outbreaks of botulism. Four conditions must be fulfilled for foodborne botulism to occur:

1. the food must be contaminated
2. spores must survive processing or be able to recontaminate
3. the food must support growth and toxin production
4. the food must be acceptable for consumption without heating sufficient to destroy the botulinum toxin.[71]

The toxins from psychrotrophic *C. botulinum* are heat sensitive and because fresh packed or unpacked fish is cooked before consumed, this is a further safeguard against botulism. Fish used for raw consumption in Japan is extremely fresh, and therefore this poses no extra risk in terms of botulism.

Other Bacterial Pathogens. Many of the diseases transmitted by consumption of raw bivalve mol-

*Spores of *C. botulinum* type E g^{-1}.

luscs can also be transmitted by raw fish. However, it should be emphasized that, as opposed to the bivalve molluscs, there is no accumulation of the pathogenic agent(s) in the fish. An outbreak of cholera in Peru was caused by consumption of ceviche (a lemon-marinated raw fish).[209] As a result, a number of Western countries prohibited the importation of fish products from South America. This may have been a dramatic overreaction, because *V. cholerae* occurs widely in the marine environment and because the excellent sanitary infrastructure in Europe will not allow an isolated incident to spread.[121,193] In general, vibrios are common causes of foodborne disease in countries such as Korea and Japan where large amounts of raw fish are consumed,[163] and in particular *V. parahaemolyticus* gastroenteritis has been linked to consumption of raw fish in Japan.[224]

Pathogenic bacteria able to grow at low temperatures, eg, *A. hydrophila*, *Y. enterocolitica*, and *L. monocytogenes* will all be outgrown by the Gram-negative spoilage microflora during chilled, aerobic storage of fish. Concerns have been raised about the risk of growth of these organisms in fish packed in modified atmosphere; however, several studies have shown that CO_2 at low temperature efficiently inhibit growth on fish of all three organisms.[58,211]

Biogenic Amines (Histamine, etc). Biogenic amines have specifically been associated with fish from the scombroid family (tuna, mackerel) but can occur also in other fish species like mahi-mahi or sardines. The amines are formed by bacterial decarboxylation of various amino acids and many bacteria are capable of producing biogenic amines.[251] Members of the Enterobacteriaceae, particularly *Morganella morganii*, are by far the most potent producers and the decarboxylation normally takes place only at high temperature. Klausen and Huss[150] showed that histamine was not formed in mackerel stored at 0°C but more than 500 ppm could be detected after 3 days at 10°C. However, histamine was also formed in fish stored at 0°C after temperature abuse (48 hours at 10°C) although numbers of histamine-forming bacteria did not increase further. This indicates that the preformed enzyme may be active at low temperatures. Other studies have shown histamine formation at low temperatures[3] and this may be attributed to activity of psychrophilic photobacteria that have been shown to decarboxylate histidine.[192,271]

Parasites. Some of the parasites present in the aquatic environment are pathogenic to man and their presence in fish is both a safety hazard and an aesthetic problem. Most of the parasites have complex life cycles passing through several intermediate hosts[27] including gastropods or crustaceans, and infect humans ingesting fish feeding on these infected organisms. Studies of parasitic infections related to seafood have primarily focused on nematodes in the *Anisakidae* family, which covers species such as *Anisakis simplex* (herring worm), and *Pseudoterranova decipiens* (cod worm). However, cestodes (tapeworms) and trematodes (flukes) have also been involved in human infection.[121,204] It is estimated that 40 million people throughout the world, particularly in Southeast Asia, are affected by trematode infections primarily caused by consumption of raw plants or raw/undercooked freshwater fish.[4] In general, parasitic infections are caused by consumption of raw (unheated) and undercooked fish products. Pond hygiene (eg, removal of intermediate hosts like snails) is important in prevention of parasitic infections from aquaculture fish. Most of the parasitic population is found in the visceral organs, which normally are removed before the fish is consumed. Roepstorff et al.[227] found that 95% to 98% of herring viscera were infected with *Anisakis simplex*, whereas only 2% to 6% and 0% to 1% of belly flaps and fillets were infected, respectively. Some studies show that the nematodes migrate from the intestines into the flesh during storage and gutting is therefore important in prevention of disease. However, no migration was detected in heavily infected herring stored in ice, in chilled seawater, or at 10°C for up to 5½ days.[227] EU[69] requires that fish are visually inspected for parasites and that fish used for particular products are frozen for 24 hours at –20°C (see below). Cooking will eliminate the risk, as the larvae are killed by exposure to 60°C for 1 minute[204] or even by 55°C for 1 minute (Huss unpublished data).

Spoilage

Microbiology of Fish and Shellfish Stored in Ice. On the surface of fish, bacteria colonize the scale pockets and during storage they invade the flesh by moving between the muscle fibers. Murray and Shewan[195] found that a very limited number of bacteria invaded the flesh during iced storage, and bacteria have been detected by microscopy in the flesh when the number of organisms on the skin surface increased above 10^6 cfu cm^{-2}.[228] Because only a limited number of organisms actually invade the flesh and microbial growth mainly takes place at the surface, spoilage is probably to a large extent a consequence of bacterial enzymes diffusing into the flesh and nutrients diffusing to the outside.

Bacteria on fish caught in temperate waters enter the exponential growth phase almost immediately after the fish have died.[111,146] This is probably because the microflora is already adapted to the chill temperatures. During ice storage, the aerobic count increases with a doubling time of approximately 24 hours and will, after 2 to 3 weeks, reach numbers of 10^8–10^9 cfu g^{-1} flesh or cm^{-2} skin. The bacteria on fish caught in tropical waters often pass through a lag phase of 1 to 2 weeks if the fish are stored in ice, thereafter exponential growth begins and the numbers reach a level similar to that on temperate water fish when spoiled.[97,102,182,255] The delay before growth of psychrotrophs on iced, stored tropical fish is one of the factors explaining the long shelf life of these fish stored in ice.[95]

The composition of the microflora changes dramatically during storage. Thus, during aerobic iced storage, the microflora is composed almost exclusively of *Pseudomonas* spp. and *S. putrefaciens*. This is true for all fish and shellfish whether caught or harvested in temperate[101,169] or subtropical and tropical waters (Table 21-8).[40,103,159,172,238]

S. putrefaciens is very important as a spoilage bacterium of iced fish (see below). The bacterium was originally associated with the *Achromobacter* group but was later placed in the *Pseudomonas* group IV.[243] Based on percentage of guanine + cytosine (GC%) it was transferred to the genus *Alteromonas*,[162] but on the basis of 5S RNA homology it was reclassified to a new genus, *Shewanella*.[180] *S. putrefaciens* has long been recognized as a very heterogenous species in general comprising the following two large groups: (1) psychrotrophic organisms, unable to grow in 6% NaCl found on fish and in cold environments, and (2) mesophilic, halotolerant organisms growing in 6% to 8% NaCl. The latter group can occur as opportunistic pathogens causing wound infection and bacteremia.[28,65,170,219] Recently, it was suggested that the mesophilic group be reclassified in its own species, *Shewanella alga*.[84,201] *S. alga*, apart from being an infectious organism, is also of interest in fishery science due to its possible ability to produce the pufferfish toxin, tetrodotoxin.[245]

S. putrefaciens is the specific spoilage bacterium of marine temperate water fish stored aerobically in ice and the number of *S. putrefaciens* is inversely linearly related to remaining shelf life of iced cod[146] (Figure 21-2). *S. putrefaciens* usually constitutes 1% or less of the microflora of fresh fish[39] but increases relative to the aerobic count and constitutes 30% to 90% of the microflora at point of spoilage.[39,146]

Pseudomonas spp. are the specific spoilers of iced stored tropical freshwater fish[103,172] and are also, together with *S. putrefaciens*, spoilers of marine tropical fish stored in ice[40,91,97] (Tables 21-8 and 21-9). *S. putrefaciens* has been isolated from tropical fresh waters, but does not appear to be important in the spoilage of iced freshwater fish from tropical waters.[103,172] This may be due to occurrence of very low numbers and the inability of the organism to compete with high numbers of antagonistic pseudomonads.[99,100]

Vacuum packing and subsequent iced storage of fish from temperate marine waters reduces the number of *Pseudomonas* spp. but *S. putrefaciens*, which is capable of anaerobic respiration using TMAO as electron acceptor, grows to levels of 10^5–10^8 cfu g^{-1}.[55,146] Numbers below 10^8 cfu g^{-1} are unlikely to be important in spoilage and consequently other organisms must be involved. Jørgensen et al.[146] observed that vacuum packed cod contained high numbers of some very large, almost yeast-like cells and suggested that these were involved in the spoilage. These cells are *P. phosphoreum*,[55] a marine vibrio that has been overlooked because it is killed by exposure to temperatures of 45°C used in pour plating.[269] It is easily isolated from intestines of various fish.[52,269] The organism has a very high spoilage activity, producing between 10- and 100-fold more TMA per cell than *S. putrefaciens*[52] but does not cause such foul off-odors as *S. putrefaciens*,[270] probably because it does not produce volatile sulfides.[51,55,270] The spoilage of vacuum packed fish from temperate marine waters is caused by these two bacteria and differences in initial numbers of *S. putrefaciens* and *P. phosphoreum* probably decide which of the two becomes most important. While abundant data exist on marine fish, little is known about the spoilage bacteriology of vacuum packed freshwater fish. It is unlikely that *P. phosphoreum* plays a major role in the spoilage of freshwater fish as it is sodium requiring. Hussain et al.[132] found while the initial flora (10^4 cfu g^{-1}) on trout was dominated by Gram-negative organisms (*Pseudomonas, Moraxella, Flavobacterium*), 4 weeks of iced storage of vacuum-packed trout selected for Gram-positive bacteria (*Micrococcus, Bacillus, Lactobacillus*), which reached 10^8 cfu g^{-1}. However, pour plating was used in this work, eliminating any very heat-sensitive organisms.

CO_2 packing of marine fish from temperate waters inhibits growth of organisms like *Pseudomonas* and *S. putrefaciens* and their numbers rarely exceed 10^5–10^6 cfu g^{-1}. Similar changes are seen for meat products[50] and result in dramatic extensions of shelf life. However, compared with meat no or only limited extension of shelf life is obtained by packing fish in a CO_2 atmosphere.[33,34,55,80] The development of TMA in CO_2 packed cod is, as shown in Figure 21-3A, enhanced compared with that in aerobic storage.[33,55] The presence and subsequent growth of CO_2-resis-

tant TMA-producing *P. phosphoreum* to levels of 10^7–10^8 cfu g^{-1} explains these observations.

In iced fish stored aerobically, spoilage is associated with the development of 10^8–10^9 cfu g^{-1} of specific spoilage bacteria. In chilled fish packed under CO_2, spoilage occurs with 10^7 *P. phosphoreum* g^{-1}.[55] This is because the very large size (5 μm) of the bacterium results in a much higher yield of TMA per cell than for *S. putrefaciens*[52] and thus a higher spoilage activity.

Carbon dioxide and vacuum packing of fish caught in freshwater or warmer waters where these particular heat-sensitive, sodium-requiring *P. phosphoreum* are probably not as common as in temperate marine waters result in decrease in TMA production (Figure

21-3B) and the microflora becomes dominated by various Gram-positive organisms, mainly lactic acid bacteria.[18,159,160,202,207]

The changes in distribution between Gram-negative and Gram-positive microorganisms in CO_2 packed fish from warm waters are shown in Table 21-9. In some trials, TMA can be detected later in the storage,[202,213] and therefore some TMAO-reducing organisms must be present. Table 21-10 gives a summary of the specific spoilage bacteria of chilled stored fish from both temperate and tropical waters.

Microbiology of Fish and Shellfish Stored at Ambient Temperatures. During ambient storage of tropical fish and shellfish, a level of 10^7–10^9 mesophilic cfu g^{-1} is reached in 12–24 hours.[92,101,102] The microflora is dominated by mesophilic *Vibrio* or *Aeromonas* spp.[92,103,238] and, particularly if the fish are caught in polluted waters, mesophilic Enterobacteriaceae.[97] At ambient temperature, motile aeromonads are the specific spoilers of aerobically stored freshwater fish.[16,92,103] A large proportion of the flora on ambient-stored mackerel consisted of *S. putrefaciens,* indicating that this bacterium may also take part in the spoilage.[19]

Biochemical Changes Caused by Bacterial Action. Comparison of the chemical compounds that develop in naturally spoiling fish and sterile fish has shown that most of the volatile compounds are produced by bacteria.[239] These include TMA, volatile sulfur compounds, aldehydes, ketones, esters, hypoxanthine as well as other low molecular weight compounds. The substrates for the production of volatiles are TMAO, sulfur-containing amino acids, carbohydrates (eg, lactate and ribose), nucleotides (eg, inosine monophosphate and inosine), and other NPN molecules. The amino acids are particularly important substrates for formation of sulfides and ammonia (Table 21-11).[109,110,222] Lerke et al.[168] separated fish juice into a protein and a nonprotein fraction and found that the nonprotein fraction of a fish juice spoiled in the same way as the whole juice, whereas only faint off-odors were detected in the protein fraction of the juice. Although some authors have used the number of proteolytic bacteria as indicators of spoilage, the turnover of the protein fraction is not of major importance in spoilage of fresh fish. The initial aerobic growth on fish is dominated by bacteria using carbohydrates as substrate and oxygen as terminal electron acceptor with the concurrent production of CO_2 and H_2O. This results in the formation of anaerobic or microaerophilic niches on the fish. This does not, however, necessarily favor the growth of anaerobic bacteria as some of the bacteria present on fish are able to carry out a respiration using other molecules as electron acceptor. It is typical that many of the specific spoilage bacteria on fish are able to use TMAO as electron acceptor in an anaerobic respiration.

*Assumed to be the most likely spoilage bacteria as typical marine bacteria are not present.

Trimethylamine (TMA). A major aspect of fish spoilage is the reduction of TMAO to trimethylamine (TMA) by microorganisms, resulting in the typical "fishy" odor of spoiled fish. Spoilage of fish by reduction of TMAO is mainly caused by *S. putrefaciens, P. phosphoreum, Vibrio,* and *Aeromonas* spp. and members of the Enterobacteriaceae (Table 21-11).[66,222,233,236,249] The ability of bacteria to reduce TMAO and/or produce H_2S can be tested in specific media and/or with specific methods.[101,162,269]

Sulfides. Many bacteria identified as the cause of spoilage produce one or several volatile sulfides. *S. putrefaciens* and some *Vibrionaceae* produce H_2S from the sulfur-containing amino acid L-cysteine.[101,250] In contrast, neither *Pseudomonas* nor *P. phosphoreum* produces significant amounts of H_2S. Thus, hydrogen sulfide, which is typical of spoiling iced cod stored aerobically, is not detected in spoiling CO_2 packed cod.[55] Some lactobacilli growing in lightly preserved fish products (eg, *Lactobacillus saké*) produce H_2S.[20,263] Methyl mercaptan (CH_3SH) and dimethyl sulfide (($CH_3)_2S$) are both formed from methionine.[109] Taurine, which is also sulfur containing, occurs as free amino acid in very high concentrations in fish muscle and disappears from the fish flesh during storage but this is believed to result from leakage rather than bacterial attack,[242] although both pseudomonads[244] and several members of Enterobacteriaceae may catabolize taurine.[268] Spoilage by *Pseudomonas* spp. results in fruity, rotten, sulfhydryl odors[91,102,103] because of formation of aldehydes, ketones, esters, and sulfides.[67,189,190] The fruity off-odors produced by *Pseudomonas fragi* originate from monoamino-monocarboxylic amino acids.

Hypoxanthine. The development of TMA is in many fish species parallelled by a production of hypoxanthine (Hx). Hx has a slightly bitter flavor, and can be formed by the autolytic decomposition of nucleotides, but can also be formed by bacteria; the rate of bacterial formation is higher than that by autolysis. Both Jørgensen et al.[146] and Dalgaard et al.[55] showed a linear correlation between the contents of TMA and Hx during iced storage of packed cod. Several of the spoilage bacteria including *Pseudomonas* spp.,[256] *S. putrefaciens,*[95,145,270] and *P. phosphoreum*[270] produce Hx from inosine or inosine monophosphate. While Hx does not cause spoilage off-odors, it may be used as a spoilage index in some fish.

Detection of Specific Spoilage Bacteria from Fresh and Packed Fish. Several methods have been developed to enumerate spoilage bacteria from fish and shellfish.[98] The ability of certain spoilage organisms, particularly *S. putrefaciens,* to produce H_2S (Table 21-11) has been used in several media in which H_2S is precipitated with ferrous ions as black FeS.[101,169] When iced fresh fish is investigated, the majority of bacteria forming black colonies on Iron Agar are *S. putrefaciens,*[52,101,145] although *Vibrionaceae* capable of forming H_2S from cysteine can also occur, especially in the warm summer months.[101,103] The ability of *S. putrefaciens* to form a red/brown pigment has been used in the gelatine-iron medium of Long and Hammer[176] and in a modified version[269] also suitable for enumeration of *P. phosphoreum,* which appeared as small frosted glass-like colonies.

Reduction of TMAO is used in the conductometric quantification of spoilage bacteria.[90,94,146] The de-

Anaerobic rods	–		?	+	?	?	*sous-vide* fish

tection times (DTs) are typically below 24 hours and the DTs in a TMAO-containing medium were inversely proportional to the number of black colonies on Iron Agar.[94,146] A conductometric method based on TMAO reduction for specific detection of *P. phosphoreum* was recently developed; selectivity is obtained by simulating the conditions in packed fish, ie, using CO_2 incubation.[56]

Monoclonal antibodies against *S. putrefaciens* have been developed with the purpose of establishing a rapid detection method.[83] However, the lower detection limit of immuno-based methods is 10^6 cfu g^{-1}. Several detection schemes have recently, with success, used immunomagnetic capture to concentrate bacteria from a sample. We have tried to use *S. putrefaciens* specific antibodies in such a procedure. Unfortunately, the general excellent ability of fish bacteria to adhere to surfaces has made it impossible to prevent nonspecific binding of bacteria to the magnetic bead, and thereby to achieve a *specific* capture of the *S. putrefaciens*. An rRNA probe for specific detection of *S. putrefaciens* has been developed,[62] however, this has not been evaluated using *S. putrefaciens* of fish origin.

21.5 MICROBIOLOGICAL HAZARDS IN FISH AND SHELLFISH PRODUCTS

Storage of fresh fish at various temperatures almost exclusively selects for Gram-negative bacteria (except for packed tropical fish) and the specific spoilage bacteria and their metabolism has been extensively studied. The combination of chilling with the addition of low levels of salt and chemical preservatives (lightly preserved fish products) causes a dramatic shift in the microbiology and both microbiological health hazards as well as microbiological spoilage become much more complex as several groups of organisms may grow and interact. Particularly, the spoilage of this type of product is not well understood. The microbiology of more heavily preserved fish products (eg, heavily salted or heated products) is, compared with fresh fish, better understood, perhaps because only few bacterial species are able to survive and grow.

21.5.1 Lightly Preserved Seafood Products

This group includes fish products preserved by low levels of salt (<6% [w/w] NaCl in the water phase) and, for some products, addition of preservatives (sorbate, benzoate, NO_2^-, or smoke). The pH of the products is high (>5.0), and they are often packaged under vacuum and must be stored and distributed at chill temperatures (≤5°C). This is a group of high-value delicatessen products (cold-smoked, pickled ["gravad"], or marinated fish, brined shellfish) that are typically consumed as ready-to-eat products with no heat treatment.

Cold smoking of fish involves salting (pickling, brining, or more common today, salting by injection), drying for 1 to 6 hours at 20° to 28°C and smoking at a maximum of 30°C for 3 to 6 hours.[130] The products usually have a shelf life of 3 to 6 weeks at 5°C. Gravad fish is a typical Scandinavian product where fish fillets (salmon, halibut, trout) are sprinkled with salt, sugar, and spices and left to ripen for 1 to 2 days at chill temperatures. Often this

Next Page

product is made at home without control of salt levels or temperature; particularly homemade gravad fish has been implicated as a vehicle for botulism.[121] Brined products are typically made from cooked crustaceans (shrimps, crabs, lobster meat), which are peeled and put into a brine with salt, carbohydrate, and preservatives such as sorbate and benzoate. Glucose has been used but may result in slime formation due to growth of *Leuconostoc* spp., whereas sugar alcohols give the sweet flavor but cannot be used as substrate in slime formation.

As some psychrotrophic pathogenic bacteria are able to survive and grow in lightly preserved fish products, the fish industry and consumers have recently focused on alternative means of preservation, eg, the use of bioprotective cultures, bacteriocins, enzymes, or cationic peptides. The bacteria or compounds are used to inhibit or delay the growth of pathogens or spoilers *without* affecting the sensory attributes of the product. As described below, particularly the presence and growth of *L. monocytogenes* in lightly preserved fish products is of major concern and use of lactic acid bacteria,[140] lysozyme,[142] protamine,[143] or nisin[200] have all proved successful in preventing or delaying the growth of this organism under conditions mimicking those in lightly preserved fish products or in real products.

Health Hazards

Lightly preserved fish products constitute, next to the raw bivalve molluscs, the most dangerous group of fish products.[121] Almost any of the pathogenic organisms listed in Table 21-2 may be transferred via these types of products. The occurrence of the indigenous organisms obviously cannot be prevented. However, prevention of disease relies on inhibition of growth by keeping levels of the contaminants low, ensuring a proper salt concentration, and distributing at chill temperatures.

Clostridium botulinum. The psychrotrophic nonproteolytic type B, E, and F strains are, under otherwise optimal conditions, able to grow at temperatures above 3.3°C and in low salt concentrations (<5% NaCl).[120] However, in chilled fish products (5°–10°C) less salt is needed to inhibit growth than at higher temperatures (Table 21-12). Also, pH interacts with NaCl (or water activity [a_w]), thus at 20°–30°C, *C. botulinum* Type E germinated and grew at a_w of 0.96 (approx. 5% NaCl) at pH 7.0, whereas the tolerance was only a_w 0.98 (approx. 3% NaCl) at pH 5.5.[17] High inocula (10^7–10^8 spores ml^{-1}) were used in this study. Using a lower inoculum of 10^4–10^5 spores of nonproteolytic *C. botulinum* ml^{-1} meat medium with 2.5% NaCl, it was similarly found that at 5°C growth occurred after 24 to 27 days at pH 6.5 and not until after 31 to 47 days at pH 5.6.[93] Vacuum packing enhances toxin production in smoked fish[129] but, as mentioned, the positive redox potential of fish may be an additional hurdle preventing growth in salted fish.[129] Several incidents of botulism associated with commercially produced smoked vacuum packed fish have been reported, but in all cases the packed fish was temperature abused.[5]

Overall, the combination of low temperature (≤5°C), a minimum of 3% to 3.5% NaCl in the water phase, and—for brined shrimp—the reduction in pH to 5.5 ensures the safety of lightly preserved fish products with respect to botulism. In over 75% of the incidents in which botulism has been caused by fish products, these have not been produced commercially.[186] Where commercial products have been involved, this has been due to post-process contamination of canned

fish, temperature abuse, or to faulty salting and/or fermentation (see Sections 21.5.2 and 21.5.3).

Listeria monocytogenes. Much research has been directed to the study of occurrence and growth of *L. monocytogenes* in lightly preserved fish products. The organism is a frequent contaminant in the raw material;[130] it survives the salting and cold-smoking process (≤30°C), and it is able to grow in the finished product at chill temperature.[23,118,140,231] Recently, six cases of listeriosis in Wärmland in Sweden were linked to the consumption of cold-smoked fish products; several typing methods showed that strains isolated from two of the patients were identical to strains isolated from the cold-smoked and gravad rainbow trout.[73]

L. monocytogenes may be found on up to 75% of cold-smoked salmon and other lightly preserved fish products.[21] Rawles et al.[212] reported that 13 of 126 freshly cooked blue crab samples were positive for *L. monocytogenes* with levels of fewer than 100 g^{-1}, and other studies similarly report low levels.[80,130] Danish investigations have recently found that 24% of freshly produced (and packed) cold-smoked salmon were positive for *L. monocytogenes* with 18% containing less than 10 g^{-1} and 6% containing between 10 and 100 g^{-1}.[123,144] An important prerequisite for control of *L. monocytogenes* in these products is knowledge about the contamination route. A high correlation was found between occurrence of *L. monocytogenes* in the seawater and on the raw material.[130] Low prevalence of *L. monocytogenes* was found in three Swiss fish farms with 9 of 36 water samples positive and only 5 of 45 fish samples positive.[137] None of 27 samples taken immediately after cold smoking was positive for *L. monocytogenes*, and only 1 of 49 samples of finished product was positive. Using multilocus enzyme electrophoresis, Rørvik et al.[232] found that the *L. monocytogenes* strains isolated from cold-smoked salmon were different from the isolates from seawater, indicating that the contaminants could not be linked to the raw material. However, other studies have concluded that the raw material is the most likely contamination source although a clear contamination route has not been found.[72] As the source of contamination is not known and as the preserving conditions do not prevent growth, no critical control point giving full control can be identified for the hazard.[130]

Numerous studies have shown that inoculated *L. monocytogenes* grow well in cold-smoked salmon at chill temperatures (4°–5°C) with 1–2 log increase per week.[231] However, in a review of published data, it was concluded the growth of naturally occurring *L. monocytogenes* in cold-smoked fish is often much slower than predicted by models.[53] At the end of commercial shelf life (storage at 5°C), 31% of samples of cold-smoked salmon were positive for *L. monocytogenes* with 27% having fewer than 10^2 g^{-1}, 2% between 10^2 and 10^3 g^{-1}, and 2% between 10^3 and 10^4 g^{-1}.[123,144] This indicates that the naturally occurring *L. monocytogenes* grew much more slowly than inoculated strains. Jay[134] suggested that the harmless microflora could prevent the proliferation of pathogens, and certainly lightly preserved fish products become dominated by lactic acid bacteria highly antagonistic against *L. monocytogenes.*[139]

Complete elimination of *L. monocytogenes* from this type of product cannot be achieved,[12] but prevention of foodborne disease can be obtained by keeping the number of *L. monocytogenes* very low. This can be done by observing strict Good Manufacturing Procedures.[87,137] A recently proposed microbiological criterion for *L. monocytogenes* in cold-smoked salmon using a three class attribute sampling plan, is $n = 5$, $m = 10$ g^{-1} and $M = 100$ g^{-1} and $c = 1$.[130] This contrasts to the US where a "zero tolerance" (absence in a 50 g sample) is the current limit for ready-to-eat products, although, based on recent assessment of the widespread alimentary exposure to *L. monocytogenes*, it has been suggested that some relaxation of this limit may be possible, but that any change would have to be carefully monitored.[114]

Aeromonas *spp.* Motile *Aeromonas* spp. (*Aeromonas hydrophila*), which occur naturally in the aquatic environment, are able to grow at chill temperatures and can frequently be isolated from fish products.[156] It has been speculated for years that the motile aeromonads may be implicated in foodborne disease,[152,158,188] but convincing epidemiological evidence is lacking. To our knowledge only one report[7] documents that an isolate from a patient with diarrhea was identical, by ribotyping, to strains isolated from a shrimp cocktail. As motile aeromonads in general are sensitive to chilling, salt, low pH, and smoke,[96] they are unlikely to constitute a serious health hazard in lightly preserved fish products.

Histamine. Histamine may be formed in lightly preserved fish products and levels between 32 and 195 mg kg^{-1} have been found in some samples of cold-smoked salmon. This is above the maximum limit of 20 mg 100 g^{-1} allowed by EU regulation,[69] however, lightly preserved fish products are not linked by epidemiological data to scombroid toxicity. The development of amines in lightly preserved fish products may result from lactic acid bacteria, some of which are able to produce biogenic amines.[165] Also, in products like matjes herring, the formation of biogenic amines has been linked to the lactic acid microflora.[199] However, Leisner et al.[165] showed that although several carnobacteria isolates were able to produce tyramine none produced histamine.

Parasites. The European legislation requires that fish raw material used for production of matjes herring, and cold-smoked fish (wild salmon, herring, mackerel, sprat, cod, and halibut) be frozen at least 24 hours at –20°C[69] because parasites are not killed by the temperatures and salt levels used in cold smoking. However, none of 3,700 fillets of farmed Atlantic salmon from Norway and Scotland was found to be infected by anisakid larvae,[10] and the legislation therefore does not apply to reared salmon.

Spoilage

Spoilage of lightly preserved fish products is mainly caused by bacterial action. Truelstrup Hansen et al.[265] found that cold-smoked salmon with reduced bacterial count was rejected by a sensory panel due to textural changes (soft and mushy), whereas the off-odors and off-flavors (putrid, sour, bitter) associated with spoilage developed in samples with natural levels of bacteria.

During chill storage (5°–10°C), the microflora of vacuum packed lightly preserved fish products becomes dominated by lactic acid bacteria. During storage of cold-smoked herring at 10°C, lactic acid bacteria increased from 10^4 cfu g^{-1} to 10^7 cfu g^{-1} after 3 weeks and 10^8 cfu g^{-1} after 6 weeks.[181] Similar data were reported for cold-smoked salmon[34,42,264] (Figure 21-4), and sugar-salted ("gravad") fish.[165] Lactic acid bacteria were found to be the dominating flora in several samples of matjes herring[199] and in lightly salted lumpfish roe.[20] High levels of lactic acid bacteria may be present for several weeks before the product is rejected for sensory reasons, and it has even been suggested that the often long keeping time of cold-smoked fish is a consequence of the development of an antagonistic flora of lactic acid bacteria[181] because they may prevent proliferation of more potent Gram-negative spoilage bacteria.

Little is known about the composition of the lactic acid bacteria group. Hildebrandt and Erol[112] found that one-third of the lactic acid bacteria on vacuum packed cold-smoked salmon were acid-sensitive carnobacteria, and a high fraction of *Carnobacterium* spp. were also found on sugar-salted fish.[165] In contrast, Truelstrup Hansen[263] reported that *L. curvatus* was the most frequently occurring lactic acid bacteria, and neither Mauguin and Novel[184] nor Jeppesen and Huss[139] found carnobacteria to be the dominant group in lightly preserved fish products. It may appear that the product either becomes dominated by carnobacteria or by *Lactobacillus* spp.

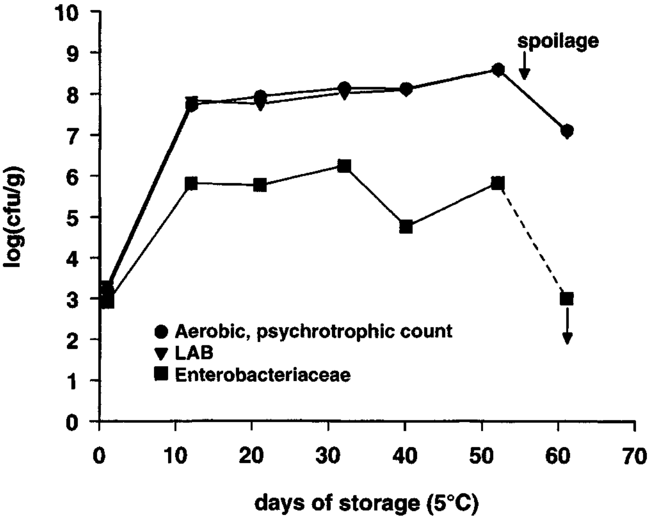

Figure 21-4 Changes in Count of Psychrotrophic, Aerobic Bacteria (●), Lactic Acid Bacteria (▼), and *Enterobacteriaceae* (■) during Storage of Vacuum Packed, Cold-Smoked Salmon (NaCl = 4.6% w/w in Water Phase) at 5°C. *Source:* Adapted with permission from L. Truelstrup Hansen, T. Gill, and H.H. Huss, Effects of Salt and Storage Temperature on Chemical, Microbiological and Sensory Changes in Cold-Smoked Salmon, *Food Research International*, Vol. 28, pp. 123–130, © 1995, Elsevier Applied Science.

Until recently, it was believed that the lactic acid bacteria were of little importance for the sensory changes during storage of fish products. Leisner[164] showed that no or very faint off-odors were produced by lactic acid bacteria compared with the very obnoxious off-odors produced by Gram-negative spoilers. However, several lactic acid bacteria were able to produce the off-odors (sour, cabbagy, sulfurous) associated with spoilage of cold-smoked salmon.[263] Furthermore, a strain of *L. saké* produced H_2S during growth on cold-smoked salmon. Counts of lactic acid bacteria in inoculated blocks of vacuum packed cold-smoked salmon reached 10^8 cfu g^{-1} after 10 days at 5°C but off-odors were not detected until after 3 weeks.[263]

Although most studies report dominance of lactic acid bacteria in vacuum packed cold-smoked fish, the chemical changes during storage vary as does the composition of the remaining microbial flora. The TMA content of cold-smoked salmon sometimes increases to 25–30 mg TMA-nitrogen 100 g^{-1},[42] whereas other samples in the same study contained only low levels (5 mg TMA-N 100 g^{-1}), and it has been concluded that TMA could not be used as an objective quality indicator of vacuum packed cold-smoked salmon.[264] The concentration of hypoxanthine increased during storage of vacuum packed cold-smoked salmon from 1–3 μmol g^{-1} to 5–7 μmol g^{-1} at rejection[34,264] and has been suggested as chemical spoilage indicator.[264]

The reason for the variability in the chemical composition of spoiled lightly preserved fish products is probably related to a yet not understood variation in the bacterial spoilage flora. Spoiled lightly preserved fish products may contain low (10^3 cfu g^{-1}) or high (10^6–10^7 cfu g^{-1}) levels of Enterobacteriaceae, *Brochothrix thermosphacta*, yeasts, and *P. phosphoreum*.[34,42,165,265] Truelstrup-Hansen[263] concluded that one of the three following different microfloras were present when cold-smoked salmon was rejected for sensory reasons: (1) lactic acid bacteria (10^7–10^9 cfu g^{-1}), (2) lactic acid bacteria and Enterobacteriaceae (10^7–10^8 cfu g^{-1}), and (3) *P. phosphoreum* (10^6–10^7 cfu g^{-1}) with occasional high levels of lactic acid bacteria. It is likely that bacterial interactions are important during spoilage of lightly preserved seafood products and Borch et al.[26] found that the spoilage profile of *Lactobacillus* spp. in cooked meat products was dependent on the presence or absence of *Hafnia alvei.*

The Enterobacteriaceae growing in lightly preserved fish products have been identified as psychrotrophic *Hafnia alvei*, *Serratia liquefaciens*, or *Enterobacter* spp. All strains produce spoilage off-odors and reduce TMAO but the ability to produce H_2S from protein substrates varies,[263] and little is known about their spoilage activity.

The sporadic occurrence of Enterobacteriaceae and *P. phosphoreum* probably explains why TMA develops in some storage trials and not in others. The complexity of the composition of the microflora and the variation seen is, apart from the sporadic occurrence of *P. phosphoreum*, similar to the microbiology of packed lightly preserved meat products.[26,50]

21.5.2 Semipreserved Seafood Products

Fish products with a high salt content (>6% NaCl in water phase) or pH below 5.0 to which preservatives (benzoate, sorbate, nitrate) may be added are defined as semipreserved. Typically, the European products (eg, salted and/or marinated herring, anchovies, caviar) are distributed at chill temperatures (<10°C). In these products, the raw material is not heat treated and destruction of parasites, and prevention of growth of microorganisms, relies on combinations of temperature, NaCl, and, for some, lowering of pH.

Several kinds of products from North Europe, particularly Scandinavia, are semipreserved. The raw material for marinated herring, the traditional barrel-salted herring is also a semipreserved product, where whole or partially gutted herring are placed in salt or sugar-salt mixtures (reaching approx. 20% NaCl wt/water phase). The herring are allowed to ripen at chill temperatures for several months and enzymes from the intestinal tract and the muscle are responsible for the ripening.[198] Usually, the ripened herring are filleted and placed in a marinade with acetic acid, salt, and sugar. Herring fillets that have been held in 4% to 5% acetic acid and 12% to 15% NaCl for 2 to 4 weeks may also be used as raw material for the marinading.[153] Also the raw material for caviar production is a semipreserved product and lumpfish roe is barrel salted (Table 21-13). The most typical semipreserved product of Southern Europe is anchovies (Table 21-13), which are produced in a

Table 21-13 Examples of European and Southeast Asian Semipreserved Fish Products

	European Products				*Southeast Asian Products*

	–/+		barrel-salted fish	4°–6°C			
	–		anchovies	≤10°C			

[a] CHO: carbohydrate usually added as complex carbohydrates, eg, cooked rice, cassava, or maize.

manner somewhat similar to the barrel-salted herring. Traditional ripened anchovies are made from partially gutted (or nongutted) anchovies that are placed in salt and brine and left in cans or other containers to ripen over several months.[226] The major cause of ripening is probably also intestinal enzymes.[208] As for the barrel-salted fish, aerobic nonhalophilic counts decrease during storage (to approx. 10^2 g^{-1}), and moderate growth of halophilic organisms (up to 10^4–10^5 cfu g^{-1}) is seen.[208,226]

The Southeast Asian semipreserved ("fermented") fish products may be divided into two groups: (1) one in which 20% to 30% salt is added and the fish is allowed to solubilize at tropical ambient temperature and (2) one in which lower levels of salt are combined with a carbohydrate source and a lactic acid fermentation takes place (Table 21-13).[46] Although the former group is often included in descriptions of fermented fish products, the level of bacteria (including halophiles) is very low (10^3–10^5 cfu g^{-1}).[133] The sensory characteristics of the product are probably a consequence of action of autolytic proteases rather than bacterial action. The lactic acid fermented fish products in which the salt content is lower and carbohydrates are added are receiving increasing attention.[15,46] Careful adjustment of NaCl concentration, carbohydrate source, and lactic acid starter culture is required to obtain a rapid decrease in pH,[15] and safety and sensory quality of these products is usually a close race between drop in pH and growth of pathogenic and spoilage microorganisms. Within 1 to 2 days, pH decreases to 4.5 and counts of lactic acid bacteria increase to approx. 10^9 g^{-1}.[278]

Health Hazards

Most of these products rarely, if processed and stored correctly, constitute a serious health risk as the high salt content (in some products combined with chill temperature) does not allow pathogenic bacteria to grow.[121] However, many of the reported incidences of botulism caused by fish products are due to improperly processed, semipreserved fish, often involving faulty salting or fermentation or storage at abuse temperatures.[29,186] This includes the use of poor quality raw material in which growth and toxin production of pathogens has already taken place.

C. botulinum may constitute a serious risk in semipreserved fish products. In the European semipreserved products, the risk from psychrotrophic *C. botulinum* is mainly related to usage of poor raw material as the toxin is stable in acid and salt environment (see below). The risk from mesophilic *C. botulinum* is typically caused by storage at abuse temperatures. This is unfortunately often seen for products like caviar, which contain less than 10% NaCl and must be distributed and stored at temperatures ≤10°C. However, as caviar is often packed in cans, they are sometimes placed at ambient temperature by supermarkets or consumers and this allows proteolytic types of *C. botulinum* to grow.

Fermented fish products where the salt content is lower than 10% to 12% also constitutes a serious *C. botulinum* risk. As fermentation is often carried out at ambient temperatures spores of *C. botulinum* may grow and produce toxin before the pH reaches inhibitory levels. *C. botulinum* is inhibited by pH values of 5.0 (nonproteolytic strains) and 4.6 (proteolytic strains). Fish has a high buffering capacity, but if fish is mixed with glucose (4%) and 1% NaCl, the pH drops to approximately 5–5.2 after 1 day and to 4.5 after 2 days.[267] Mixing of the fish with starchy products (eg, cassava) dilutes the buffering capacity and pH drops much more rapidly to below 4.5 within 1 day.[267] The botulinum toxin is stable in acid (pH 4.0–4.5) and salt (up to 26%) conditions[125] (Chapter 41) and once formed, further fermentation will not destroy the toxin. If the product is eaten without cooking, the risk of botulism is high. It is evident from the numerous records of botulism from various fermented fish products that this is a true high-risk group, as reviewed by Eklund[71] and Huss.[120]

Some of the risks associated with fresh fish are also present in these products, eg, marine toxins may occur also in the semipreserved product if present in the raw material. Salted anchovies have caused histamine outbreaks in the UK. However, this is believed to have been the result of formation of histamine in the raw material rather than taking place during production and ripening of the product.[226] The content of biogenic amines did not change during ripening or storage of anchovies, whereas significant production was seen after 1 to 2 days in the fresh raw material if stored at temperatures ≥8°C.[272] Most of the Gram-negative pathogenic organisms will be efficiently inhibited by the levels of salt and pH and are therefore not major problems in these types of fish products.

Nitrosamines. Nitrate is added as a preservative and coloring agent during barrel salting of some Scandinavian products, and the detection of carcinogenic nitrosamines in the product has raised concern about this addition. It has, however, also been found that the formation of nitrosamines is limited and independent of the addition of nitrate.[155]

Parasites. Fish used in pickled (marinated) products or fermented products do not receive a heat treatment necessary for destruction of parasites and as these may be present, although only in small numbers, manufacturing must guarantee their elimination. The organisms are sensitive to NaCl. Thus, Karl et al.[147] showed that in herring with 2.6% acetic acid, *Anisakis simplex* remained viable 5 to 6 weeks in 8% to 9% NaCl (in water phase) and for 10 to 12 weeks at 5% to 6% NaCl (Figure 21-5). The authors concluded that following traditional Danish procedures (presalting in 10% to 18% brine for 24 hours; brining in 10% salt and 5% acetic acid at 5°C) destroys the parasites in 5 weeks.[147]

Herring infected with the intracellular fish parasite, *Ichthyophonus hoferi,* are of poor quality (soft, slimy, and off-odorous). However, the parasite cannot grow at temperatures ≥30°C.[247] It does not infect mice and is therefore unlikely to cause disease in humans.[246]

Spoilage

The microflora of the salt-pickled European fish products have only been studied sporadically, often with the purpose of investigating the possible role of bacteria in the ripening process. Several studies have concluded that microorganisms are not important for the ripening of sugar-salted fish.[154] Similarly only low levels of bacteria ($<10^3$ cfu g^{-1}) were found in salted anchovies.[226] Knøchel and Huss[154] found that sugar-salted barrel herring could develop two spoilage patterns; one where yeast at levels of 10^5 cfu g^{-1} dominated and caused a fruity type of spoilage and one characterized by sour or putrid off-odors in which strictly anaerobic, halophilic, Gram-negative rod-shaped bacteria dominated (10^6–10^7 cfu g^{-1}). The latter was typically seen when raw material of poor quality was used because the level of TMAO was low in these fish and subsequently, the redox potential dropped more rapidly and allowed growth of true anaerobic organisms.

More heavily salted, dried fish products (eg, prepared from cod) contain 19% to 20% NaCl and 50% to 55% water. Two types of microbial spoilage can occur in these products. Halophilic bacteria (*Halococcus* spp.) that are often pigmented cause the condition known as "pink" which, apart from the formation of a reddish color in the advanced stages, causes putrid

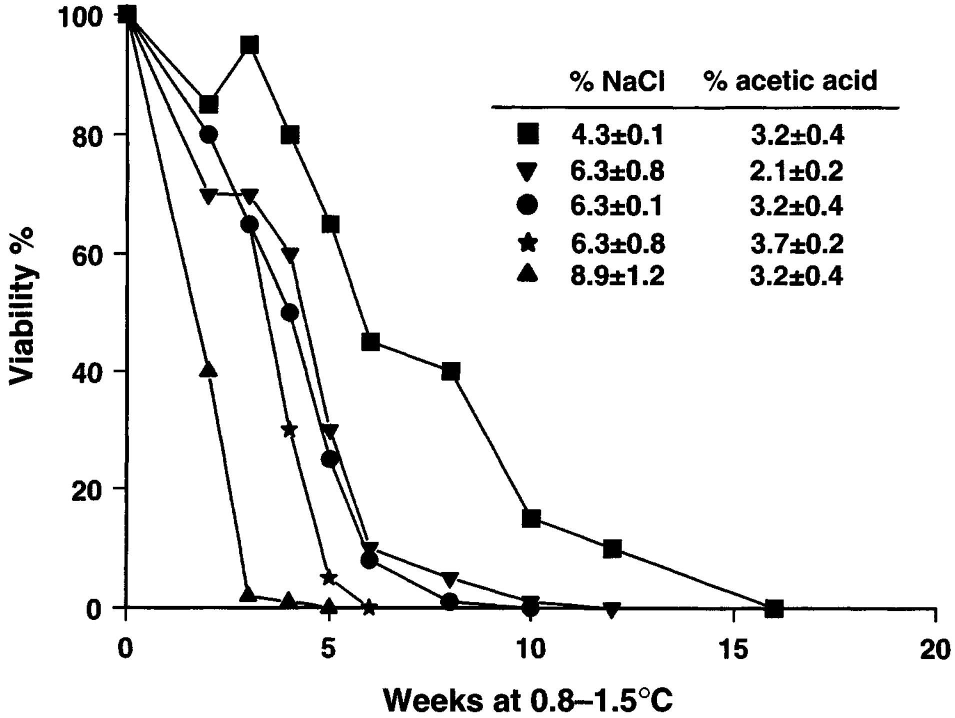

Figure 21-5 Survival of *Anisakis* Larvae in Marinated Herring Depending on Salt and Acetic Acid Concentration (% in water phase of fish tissue). Larvae were inserted (10 per butterfly fillet) in herring stored in barrels at 3°C. *Source:* Adapted with permission from H. Karl, A. Roepstorff, H.H. Huss, and B. Bloemsma, Survival of *Anisakis* Larvae in Marinated Herring Fillets, *International Journal of Food Science and Technology,* Vol. 29, pp. 661–670, © 1995, Blackwell Science, Ltd.

odors due to proteolysis.[126] Yellow, brown, and black colored molds may grow on the product causing the spoilage condition known as "dun."[126]

Little is known about the spoilage of fermented fish products; however, preliminary studies indicate that the lactic acid bacteria continue to dominate the product during storage. It is not known if spoilage of these products is caused by the activity of the lactic acid microflora or by autolytic changes.

21.5.3 Heat-Treated Seafood Products

Many seafood products receive a heat treatment as part of the processing and, depending on the temperature used, they can be classified into the following four categories with different microbiological problems:

1. Pasteurized products that are often vacuum packed and must be distributed at chill temperatures (including hot-smoked fish and Refrigerated Processed Foods with Extended Durability (REPFEDs))
2. Cooked products, eg, shrimp or cooked and breaded fish fillets, often packed and sold frozen
3. Canned (not sterilized) products
4. Commercially sterilized (canned) products

Hot-smoked fish are usually brined or dry salted and dried before smoking at an internal temperature of approximately 65°C for 45 minutes. In developing countries, the hot smoking may be a more severe process resulting in complete cooking of the meat or in a smoke-dried product. In contrast to cold-smoked fish, the proteins in hot-smoked fish are denatured.

Recently, precooked/pasteurized refrigerated foods have become very popular, particularly in catering. These products, which are not preserved by conventional chemical preservation parameters, are marketed as chill-stored products usually under vacuum or modified atmosphere and are collectively known as REPFEDs.

Pasteurized (1 minute at 77.2°–98.8°C) crab meat is typical of canned, nonsterile fish products which, as the REPFEDs, must be distributed at chill temperatures. Canned, sterilized products (eg, canned mackerel, tuna, salmon) have received sufficient heat treatment to allow distribution and storage at ambient temperature.

Health Hazards

Spores of *C. botulinum* readily survive the hot-smoking procedure and numerous studies have shown that growth and toxin production occur in the product.[71,129] Factors of importance for the time to toxin production are temperature, oxygen tension (eg, vacuum packing), salt concentration, and associated microflora. Huss et al.[129] showed that one of duplicate packs of aerobically packed hot-smoked herring was toxic after 6 days storage at 15°C, while both packs were toxic by day 16 (inoculum 10^3 spores of *C. botulinum* type E g^{-1}). If vacuum packed, both duplicate packs were toxic after 5 days at 15°C. Similarly hot-smoked whitefish with 2.8% w/v salt was not toxic after 7 days at 25°C if packed in O_2-permeable film but was toxic after 3 days if packed in O_2-impermeable film (inoculum 10^3 spores of *C. botulinum* type E 100 g^{-1}).[71] While 1.8% NaCl (w/v) was insufficient to prevent toxin production at 25°C, 3.8% prevented toxin production for 42 days at 10°C,[71] and Cann and Taylor[32] found that 3.0% NaCl prevented toxin formation for 30 days in hot-smoked trout inoculated with 10^2 spores *C. botulinum* type E g^{-1} and stored at 5°C. In hot-smoked herring that was surface inoculated with 10^3 spoilage bacteria g^{-1} and also inoculated with *C. botulinum* (10^3 spores g^{-1}), and packed in air or vacuum, toxin production occurred at the same time in both types of packs.[129] This indicated that consumption of oxygen by the associated microflora may enable growth and toxin production by *C. botulinum*. If the product is distributed at chill temperatures (≤5°C), 3% w/v NaCl is sufficient to prevent toxicity; however, at higher temperatures, more salt needs to be included. As for the lightly preserved fish products, a level of 3% NaCl combined with chill storage is necessary to prevent botulism from occurring.

L. monocytogenes is more heat resistant than Gram-negative spoilage bacteria; however, hot smoking (60°C for 20 minutes) destroyed 10^6 cells g^{-1},[136] and any risks associated with this organism in hot-smoked fish are therefore related to post-process contamination. Hot-smoked fish are virtually surface sterilized and contamination with microorganism from food handlers (eg, *S. aureus* or Enterobacteriaceae) may constitute a risk.

If the products are packed before heat treatment, post-process contamination with pathogens should obviously not occur provided that packs are properly sealed and handled, and health hazards therefore mainly concern organisms able to survive the heat treatment. The organisms of major concern in *sous vide* and REPFED foods are nonproteolytic *C. botulinum*, psychrotrophic *Bacillus cereus*, and *L. monocytogenes* as they may survive a mild heat treatment and can grow at the chill storage temperature. As many psychrotrophic Gram-negative spoilage organisms will be destroyed by the heat treatment, there is no guarantee that the product will spoil before it becomes hazardous.[5]

Due to their ability to form spores and grow at chill temperatures, nonproteolytic *C. botulinum* are of great safety concern to the REPFED industry.[178] As for *L. monocytogenes*, the composition of the substrate may strongly influence the heat resistance of *C. botulinum*, thus a $D_{82.2}$-value of 6.6 minutes was found for spores of nonproteolytic *C. botulinum* in tuna in oil, whereas oil-free fish products had D-values between 1 and 3 minutes. The subsequent chill storage period of REPFED may allow recovery of damaged cells, and studies should therefore be conducted combining heat treatment and chill storage. During experiments in which spores of nonproteolytic *C. botulinum* in a meat medium (10^6 spores 20 ml^{-1} medium) were heated at 65°C for 364 minutes, 70°C for 8 minutes, or 75°C for 27 minutes after which the medium was stored at 6°C, growth and formation of toxin occurred in all the samples within 28 days.[206] Similar experiments have not yet been conducted in fish products, and it is not known if the presence of TMAO and the positive redox potential may constitute an extra hurdle against growth of *C. botulinum*. Lysozyme is known to enhance recovery of heat-injured spores of nonproteolytic *C. botulinum*,[93,179] and because several fish contain lysozyme,[194] this may add to the risk due to *C. botulinum* in heat-treated, chilled fish products. Different countries have different recommendations for the necessary heat treatment depending on whether packed before or after heat treatment processing and depending on shelf life. However, with up to 6 weeks shelf life a heat treatment of 90°C for 10 minutes is recommended for destruction of nonproteolytic *C. botulinum*.[178]

Another potential, but not investigated, risk in REPFEDs is the growth of psychrotrophic *Bacillus cereus* (Chapter 39). In recent years, the dairy industry has paid attention to these organisms. Of 85 strains isolated from dairy products, 5 were capable of growing at 6°C, and produced toxin at 30°C.[104] Rusul and Yaakob[229] found that 164 of 187 isolates from many different foods were psychrotrophic and 82 of these were able to produce enterotoxin. In both these studies, enterotoxin production was assessed at 30° to 32°C and bears little relevance to these food products. Christiansson et al.[41] found that three-fourths of 102 psychrotrophic *B. cereus* were able to produce toxin in aerated samples of milk stored at 8°C for 72 hours, but not in nonaerated samples. The numbers of psychrotrophic *B. cereus* in foods and their growth characteristics are not known. *Bacillus* spp. grew in chill-stored *sous vide* fish, perhaps being involved in spoilage[22] (see below). This indicates that there may be a risk.

L. monocytogenes will normally be destroyed by pasteurization processes employed in the production of *sous vide* foods and other REPFEDs.[21] However, the heat resistance of the organism may vary depending on fat content and water activity; Ben Embarek and Huss[24] found that the D_{60}-value was much higher in salmon (4.5 minutes) than in cod (1.8 minutes), indicating that the lipid content of the former protected the bacteria against heat. Similar D-values have been reported for *L. monocytogenes* in various crustaceans.[21]

Cooked crustaceans, and dishes made from them, have often been implicated in foodborne diseases by *Staphylococcus aureus* and enteropathogenic Enterobacteriaceae and *Vibrionaceae*.[29,121] Typically, the heating process causes a dramatic reduction of normal Gram-negative flora and post-process contamination and some degree of temperature abuse is the usual cause of illness. The processing of several products from crustaceans involve cooking, followed by machine or manual shell removal. The latter step carries a great risk of contamination with microorganisms of human origin such as *S. auerus*. Crab that was hand picked typically contained three to four times higher levels of *S. aureus* than machine-picked meat[43]; actual levels varied from 10^2 to 10^4 g^{-1}.[43] As the product immediately after cooking is virtually sterile, the organism will grow well unless it is rapidly cooled and stored under chilled or frozen conditions.

Many of the risks described for REPFEDs also apply to the canned, nonsterile products. However, products like canned crab meat have never been the cause of botulism,[43] although it is documented that nonproteolytic *C. botulinum* may grow and produce toxin. After heating to 82.2°C for 5 minutes, Type E toxin was detected after 30 to 40 days in crab extract stored at 10°C but not detected in 75 days in crab extract stored at 4.4°C (initial inoculum 5×10^4 spores $tube^{-1}$).[166] Both storage temperature and pasteurization temperature are important parameters in controlling the botulinum hazard.

In general, it must be recommended that all fish products that are not heat treated immediately prior to consumption (ready-to-eat products), and that rely on chill temperature as the only hurdle against *C. botulinum*, should contain a minimum of 3% NaCl wt/water phase.

Canned, sterilized products pose no health risk if processed (heat treated) correctly using good quality raw materials. However, canned fish products have been implicated in several cases of histamine poisoning[260] resulting from histamine accumulated in the raw fish before thermal processing.[1] The heat processing of low-acid canned foods is specifically designed to eliminate *C. botulinum* and canned fish account for only 3% of outbreaks of botulism.[120] Botulism from canned products is caused by underprocessing and/or post-process contamination. Thus, two out of four commercially prepared fish products that have caused botulism involved post-process contamination of canned salmon.[186]

Spoilage

Hot smoking of fish will reduce the bacterial load and if the product is vacuum packed and stored at 5°C the bacterial count remains low ($<10^3$ g^{-1}) even after months of storage.[85] The quality, however, decreases as a dry unpleasant texture and flavor appears. If stored aerobically, molds and yeasts are common spoilage organisms.[85] In many African countries, hot smoking and smoke drying are widely used as means of preservation. The products are typically not salted and stored aerobically at ambient tropical temperatures. Molds of various kinds develop on the surface and are typically the cause of rejection,[70] together with insect infestation.

Little is known about the spoilage of REPFEDs; however, in products stored in chilled conditions, psychrotrophic, heat-resistant microorganisms would be expected as the main cause of microbiological spoilage. The microbial count of *sous vide* cod stored at 5°C sporadically increased to 10^6–10^8 cfu g^{-1} and extremely obnoxious and putrid off-odors developed after 4 to 5 weeks.[22] Gram-positive, motile, aerobic bacteria with oval and terminal spores were isolated and identified as a *Bacillus* species.[22]

Unusual clostridia have been found as spoilers of pasteurized crab meat,[237] and it has been reported that gasses like CO_2 or a combination of CO_2 and H_2S were produced in spoiled pasteurized crab meat in which the facultative anaerobic count was approximately 10^8 g^{-1}.[43]

Properly processed canned foods present no microbiological problems and container defects and underprocessing were almost always involved when canned products spoiled.[2]

21.6 CONCLUDING REMARKS

Many aspects of the microbiology of fish and fish products have been thoroughly investigated, and as is evident from the above, the understanding of both health hazards and spoilage is, for some products, well established. For instance, the microbiology of products that are heavily preserved (eg, iced, high salted, heat sterilized) is well understood. However, it is also clear that there are many areas that require further investigation, partly because changing, often milder processing procedures are increasingly used. This is particularly so for products in which combinations of mild preservation parameters are used.

In general, research should be focused on understanding the ecology of the microorganisms in their environment. This will, as opposed to much of the research done so far, require studies in food-relevant model systems and studies of mixed cultures. An attempt should be made to control the development of the microflora in a product, using the nonpathogenic microflora, rather than focusing on complete elimination or inhibition of the microflora.

Some of the major areas needing further investigation are:

1. the ecology of viral contaminants
2. a fuller understanding of the ecology of pathogenic bacteria associated with fish and fish products, eg, how do the organisms cope with transfer from nutrient rich (foods and humans) to nutrient poor conditions such as soil and water
3. contamination routes, eg, for *L. monocytogenes*
4. the development of better control measures for *L. monocytogenes* and other psychrotrophic pathogens
5. identification and characterization of specific spoilage bacteria in fish products, particularly the lightly preserved fish products
6. characterization of the microbiology of fermented fish products
7. the importance of bacterial interactions for growth and metabolism of spoilage and pathogenic organisms
8. risk assessment of fish products
9. assessment of advantages and risks of new preservation principles
10. the possible consequences of widespread use of antibiotics in fish rearing.

22.1 INTRODUCTION

Milk and products derived from milk have been part of the human diet throughout recorded history. Despite current controversies surrounding the nutritional status of milk, it remains an important part of our diet and is a valuable source of calcium, protein, and vitamins. The dairy industry must ensure that the dairy products we consume are of the highest quality and are safe to eat. To accomplish this a good understanding of the microbiology of milk must be maintained, even though the problems may change with the introduction of new production and processing systems. This chapter will review the current status of knowledge concerning the microbiology of milk and milk products from farm to carton, and point out some of the concerns that may arise in the future. Before microbiological issues are addressed, a brief overview of the composition of milk is provided as it is impossible to understand factors affecting the growth and survival of organisms without knowledge of the substrate availability and the food environment in which the organism is found.

22.2 MILK COMPOSITION

22.2.1 What Is Milk?

Milk is a complex source of nutrients including protein, carbohydrate, lipid, vitamins, and minerals whose primary role is to provide nourishment to the neonates of the mammalian species from which it was derived. However, milk from a variety of animals has become an important part of the human diet. The components that make it nutritious for humans also provide an ideal growth medium for many microorganisms. Although the composition varies significantly with species and breed, the typical composition of bovine milk is shown in Table 22-1.

22.2.2 Lipids

About 98% of the fat of cow's milk is triglyceride, the rest is composed of small amounts of mono- and diglycerides, phospholipid, free fatty acids, cholesterol ester, and cholesterol. The lipid contains mainly C_{16} to C_{18} fatty acids but a significant amount (about 38%) of the triglyceride contains short-chain C_4 to C_{14} fatty acids.[42] The fat in milk is present as globules surrounded by a phospholipid-rich membrane (the milk fat globule membrane).[177] Homogenization, or other mechanical stress, causes a reduction in size of the globule and makes the lipid more accessible to the action of lipolytic enzymes.

Several of the microorganisms isolated from milk are capable of hydrolyzing milk fat. In a survey of creamery silo milks in southwest Scotland, Muir et al.[176] found that the majority of isolates obtained were capable of lipolytic activity (Table 22-2). These included members of the genus *Pseudomonas* as well as Enterobacteriaceae. It is well recognized that several psychrotrophic bacteria produce heat-resistant lipolytic enzymes that can remain active even after pasteurization.[103,141,231] These enzymes also retain significant activity at refrigeration temperatures.[5,40,60,85,194,235] In the presence of other enzymes, such as protease, glycosidases, and phospholipase, whose combined effect is to break down the milk fat globule membrane, the action of lipase is enhanced.[3,39,93,153,187] It is believed that the milk fat globule membrane does not limit the activity of bacterial lipases.[84] This view is supported by results showing that only the native milk lipoprotein lipase and not *Pseudomonas fluorescens* lipase exhibited the synergy with other enzymes responsible for degrading the fat globule membrane.[93] It has been shown that *Staphylococcus aureus* can bind to milk fat globules and this results in a "biofilm-type" of growth in which the bacterial cells form a capsule.[2] The staphylococcal cells bound to the fat globule are more resistant to antibiotics than planktonic cells. It may be that several other bacteria may be able to associate with fat globules and exhibit capsule formation, which would make them more resistant to sanitizers as well as antibiotics.

The lipid composition of milk can be varied by dietary manipulation.[9] When cream was obtained from milk with high (37.2%) and low (27.8%) levels of unsaturated fatty acids, the shelf life of the cream high in unsaturates was 2.5 days longer at 8°C.[194]

22.2.3 Proteins

The major proteins found in milk are the caseins and the whey proteins comprising α-lactalbumins, β-lactoglobulins, serum albumin, and the immunoglobulins.[10] Psychrotrophic bacteria found in milk produce heat-stable extracellular proteases that primarily act on the caseins. These are degraded usually in the order κ-casein > β-casein > α-casein.[72] However, other degradation patterns have been described.[238] Proteolysis of milk usually results in gelation[72,159] and in the production of bitter and "unclean" off-flavors.[156,262] The psychrotrophic microflora found in milk do not generally degrade whey proteins; however, the lactic acid bacteria are known to denature these proteins. Proteins that can exert a considerable effect on the microflora of milk are present at low concentrations and these include lactoperoxidase, lactoferrin, and lysozyme.

22.2.4 Carbohydrates

Lactose is the principal carbohydrate found in milk, although monosaccharides (primarily glucose and galactose), oligosaccharides, and peptide- and protein-bound carbohydrates are also present, albeit at very low concentrations. Lactose is the ferment-

able carbohydrate utilized by the lactic acid bacteria during the production of cheese, yogurt, etc. Methods of transportation and metabolism of lactose vary substantially within the lactic acid bacteria.[44] Certain lactic acid bacteria can also metabolize citric acid present in milk to produce flavor compounds.

22.2.5 Vitamins and Minerals

Milk also provides a good source of vitamins and minerals for microbial growth. Thus, an ample nutrient supply coupled with a near neutral pH (6.5 to 6.8) and a high water activity ensures that milk will support the growth of a wide range of microorganisms and, as such, is a highly perishable product. The need to preserve milk has led to the development of a variety of products that rely on temperature, a reduction in water activity, or both to maintain stability.

22.3 UNFERMENTED PRODUCTS MADE FROM MILK

22.3.1 Fluid Milk

Pasteurized Milk

Milk for consumption is generally heat treated to reduce numbers of potential pathogens and, concomitantly, spoilage organisms. This is achieved by passage through a plate heat exchanger at high temperatures for short holding times (HTST pasteurization). The time-temperature combinations used vary considerably but the legal minimum requirement in most countries is at least 72°C for not less than 16 seconds.

UHT Milk

In order to create a shelf-stable product that can be stored at ambient temperatures for several months, commercial sterility is required. To achieve this without having catastrophic effects on flavor, milk is heated at very high temperatures (≥125°C) for very short holding times (1 to 5 seconds). This ultrahigh temperature (UHT) treatment can be achieved either indirectly by using a heat exchanger or by direct injection of steam into the milk. The latter is claimed to have advantages in terms of taste. No matter how the heat treatment is carried out, to maintain sterility the milk must be aseptically packaged.

22.3.2 Cream

The fat may be separated from milk by a continuous centrifugation process, which makes use of the density differences between the fat and the aqueous phase. Creams of different fat content are produced and their composition varies among countries. Typically, the fat content can vary between 12% and 55%. Creams of lower fat content are almost always homogenized. As with fluid milk, cream is heat treated to ensure safety and both HTST pasteurized and UHT creams are produced. The temperatures used in the HTST process are usually higher for cream than for milk.

22.3.3 Butter

During butter manufacture cream is churned and "worked" to produce a continuous fat phase consisting of fat globules that have coalesced, fragments of globules, and fat squeezed from the globules. The major portion of the aqueous phase is present in small discrete droplets but some of the water forms continuous channels. An accepted standard for butter in most countries is that it should not contain more than 16% water and not less than 80% milk fat. To improve the spreadability of butter attention has focused on vegetable oil–butter blends. Cream for butter manufacture is pasteurized before churning. Following pasteurization, the hot cream may also be subjected to reduced pressure in a process called vacreation. This removes undesirable feed-related taints from the butter.

22.3.4 Milk Powder

The properties of the powder are determined by the processing conditions used in its manufacture. Low-heat powders are manufactured from pasteurized milk and, in this case, the integrity of the whey proteins is intact. These powders are normally used as coffee whiteners. High-heat powders are produced from milk that has undergone a second heat treatment at 115° to 120°C for 30 seconds to 15 minutes to effectively denature the whey proteins. These powders are ideal for incorporation into bread dough. Following the initial heat treatment, the milk is evaporated to about 50% total solids and then spray dried. The evaporated milk is atomized, and the small particles that result are dried very quickly by the application of heat. The heat can be applied directly or indirectly. Although the temperatures in the drier can reach 180°C, the temperature of the particles never exceeds that of their dew point and so damage to protein is minimal. The moisture content of the powder collected from the drier is about 4%. The finer particles are collected using a cyclone.

Instantized powders that are readily soluble can be obtained by modification of the drying process to allow agglomeration of particles. Powders are removed from the drier at 8% moisture during this process and final drying is achieved on a fluidized bed.

22.3.5 Evaporated and Condensed Milks

In order for the milk protein to withstand the in-can sterilization process used in the manufacture of evaporated milks, stabilizers such as phosphates, citrate, bicarbonate, or $CaCl_2$ are added to the raw milk. The milk is heated to denature the whey proteins and then evaporated. Heat-treated skim milk concentrate is added to reduce the total solids and fat content to the required levels. Following homogenization, the evaporated milk is filled into cans, sealed, and sterilized at 120°C for 10 minutes. Evaporated milk is darker in color than pasteurized milk because of the Maillard browning that occurs at the high temperatures used in the process.

Condensed milks are manufactured in a similar way to evaporated milks but they are not sterilized. Sweetened condensed milk is made by the addition of sugar (usually sucrose) to the milk. For the retail trade, where the milk is canned, a "sugar ratio" of 63.5 to 64.5 is used but for bulk sales to confectioners, bakers, and other users a ratio of 42 is more common because of the shorter anticipated shelf life. The sugar ratio is determined from the formula:

$$\begin{array}{c}\text{Sugar}\\\text{ratio}\end{array} = \frac{\%\ \text{sugar of condensed milk}}{100 - \text{total milk solids of condensed milk}} \times 100$$

22.3.6 Ice Cream

Ice cream is manufactured from a liquid mix that may contain milk, cream, water, milk solids-not-fat, nonmilk fat, sugars, emulsifiers, stabilizers, and flavoring and coloring agents. The mix is heat treated either under HTST (usually about 80°C for at least 16 seconds) or UHT conditions (usually about 140°C for 5 seconds), homogenized, cooled, and stored at about 3°C for up to 24 hours. The mix is rapidly frozen in an ice cream freezer to temperatures in the range –5° to –7°C. During freezing air is incorporated by agitation of the mix. After freezing the ice cream may be dispensed for sale as "soft-serve" or can be packaged and hardened at –20° to –40°C.

Dairy desserts are made from ingredients similar to those in ice cream mix formulations.

22.4 MICROFLORA OF RAW MILK

22.4.1 Production of Milk

Although milk production practices differ greatly throughout the world, in most developed countries milk is collected by machine milking and transferred to refrigerated bulk storage tanks where it is held prior to transportation to processing facilities. These handling methods have resulted in a dramatic change in the microflora of raw milk brought about by selection and adaptation. However, before we investigate these changes, some background information on the sources of microbial contamination of milk would be opportune.

22.4.2 Contamination from the Udder

Contamination from Udder Infection

In healthy cows free from infection, milk emerging from the udder is essentially sterile. However, udder infections are common, and there is evidence that about 33% of dairy cattle in the United Kingdom (UK) suffer from mastitis.[27] The most common agents of mastitis are *Staphylococcus aureus*, *Streptococcus agalactiae*, *Streptococcus uberis*, and *Escherichia coli*. As well as producing visible clinical infection, less acute, subclinical states are often encountered and can only be diagnosed by examination of the milk for characteristic changes, such as elevated somatic cell counts and increases in concentrations of serum albumin and immunoglobulins in the milk. The organisms enter the udder by way of the duct at the teat tip and certain of them, such as *Staphylococcus aureus*, can colonize the duct. It is thought that machine milking plays a part in the propulsion of the organisms into the teat duct but this is by no means the only route of contamination.[27] From the duct the organisms can enter the milk and can contribute significantly to the numbers present in bulk tank samples. Bramley et al.[28] isolated *S. aureus* or mastitis-producing streptococci from 86% of milk samples analyzed but bacterial numbers were below 1×10^4 cfu ml^{-1} in 90% of these milks. However, in herds with a high incidence of *Streptococcus uberis* infections, counts in the bulk tank milk reached 1×10^5 cfu ml^{-1} in a small number of cases.

Whereas the organisms that cause mastitis do not generally grow in refrigerated milk, they are able to survive under these conditions and may be a concern from a public health aspect. It has been demonstrated that staphylococcal enterotoxins and toxic shock syndrome toxin-1 can be presynthesised in the udder and secreted into milk in cows and goats suffering from *S. aureus* mastitis.[181,265] Modern dairy husbandry practices, such as teat dipping and dry cow therapy with antibiotics, can successfully reduce the incidence of mastitis.[26,114] Hillerton et al.[115] showed that application of a mastitis control plan reduced the incidence of cows infected with mastitis caused by coagulase-positive staphylococci from 21.9% to 12.0% in a 5-year period. However, the total incidence of clinical mastitis did not change significantly because environmental organisms were responsible for 65% of all clinical cases. It has also been suggested that reductions in somatic cell counts in raw milks observed in some countries may be due to a reduction in the practice of addition of mastitic milk to the bulk supply by farmers, especially where payment schemes based on milk quality are in operation.[196]

The control of mastitis through antibiotic therapy does not come without a price. As well as the concerns over potential allergenic, carcinogenic, and mutagenic reactions in consumers who are exposed to milk containing antibiotic residues, antibiotic therapy with drugs such as β-lactams and tetracycline may result in the transfer of antibiotic resistance to human pathogens from drug-resistant organisms. However, whereas some researchers believe that the incidence of the latter is negligible,[167] there is now increasing evidence that antimicrobial drug use on farms can lead to the dissemination of antibiotic resistance via the food chain.[158] Multiple antibiotic-resistant strains of a number of organisms, including *E. coli*, *Salmonella* spp., and *S. aureus*, have been isolated from raw and pasteurized milk,[57] and there are reports of a decrease in efficacy of several antibiotics against some *E. coli* that cause mastitis.[73] Their presence in pasteurized milk may have been the result of post-process contamination or inadequate heat treatment. There is another concern that has not been adequately addressed, and that is the possibility of the development of cell-wall deficient (CWD) or L-form strains of bacteria arising in the milk supply. These CWD strains arise as a result of exposure to antibiotics or other antimicrobial agents that affect the cell wall. They are often very difficult to detect by standard culture techniques although they remain viable. The role of CWD strains in a number of diseases has been reviewed by Mattman.[155] CWD strains of *Streptococcus agalactiae*, *Staphylococcus aureus*, and *Corynebacterium pyogenes* have been implicated in bovine mastitis.[18] Sears et al.[220] found that cows infected with *S. aureus* that had been treated with cloxacillin did not secrete the classic form of the organism in their milk but CWD forms could be detected in the milk for up to 30 days. The practical significance of these findings remains to be determined.

There is evidence that significant numbers of organisms are found in milk taken aseptically from the udders of apparently healthy cows. Limond and Griffiths[147] obtained counts of about 100 cfu ml^{-1} in aseptically drawn milk, although no attempt was made to characterize these isolates. Apart from mastitis-causing organisms, other bacteria that are pathogenic to humans may infect the udder; these include *Mycobacterium bovis*, *Brucella abortus*, *Listeria monocytogenes*, *Coxiella burnetii*, and *Salmonella* spp.[259] Recent attention has focused on *Mycobacterium paratuberculosis*, which has been linked to Crohn's disease.[37]

Contamination from the External Surface of the Udder

The external surface of the udder is also a prime source of microbial contamination of milk. Bedding materials, mud, dung, soil, and other matter all readily stick to skin and are a rich source of microorganisms. Even after washing with water, the microbial count on teat surfaces can be high,[250] and the count in milk from washed udders may only be about 1 log cycle lower than from those that were unwashed.[126] However, the importance of proper washing and drying of the udder before milking for the elimination of *Listeria* spp. has been demonstrated.[121] In a study on the risk factors associated with contamination of raw milk by *Listeria monocytogenes* on dairy farms, Sanaa et al.[213] showed that poor cleanliness of cows, inadequate lighting of milking parlors and barns (which may be an indication of neglect of milking hygiene), and incorrect disinfection of towels used to dry the udder significantly increased the likelihood of contamination.

It has been suggested that bedding affords the greatest contribution to udder contamination.[49,161,225] These researchers showed that there was a reduction in bacterial levels on teats when cows were on pasture, and this was reflected in lower bacterial counts in milk during this period. The bacterial count of all types of bedding was about 5×10^9 cfu g^{-1} whereas that on pasture was approximately 8×10^7 cfu g^{-1}.[161]

The dominant microflora on the teats of cows housed in byres were micrococci,[48,49,257] but it has also been estimated that 90% of the spores found in raw milk come from this source.[161,264] The principal source of psychrotrophic spore formers (mainly *Bacillus* spp.) in milk appears to be contamination of the teat by the upper layer of soil in pasture land and by feces[161,247] but this obviously does not hold for cows that are zero-grazed. There is also a distinct seasonal effect on the incidence of psychrotrophic spore formers in milk, with the highest levels being observed in late summer and early autumn.[161,193,241] McKinnon and Pettipher[161] determined that the mean total spore count in farm bulk tank milks during the winter was 2.2×10^2 cfu ml^{-1} whereas the corresponding value in the summer was 10 cfu ml^{-1}. However, the summer milks contained about 5 psychrotrophic spores ml^{-1} compared with 0.5 ml^{-1} in milks sampled in the winter. It has been postulated that antagonistic effects of mesophilic strains of *Bacillus* spp. may influence the incidence and growth of psychrotrophic isolates in the environment or in milk.[241] *Clostridium* spores can be introduced into milk from feedstuff, especially silage, and bedding.[33,59,113] Silage is also an important source of contamination by *Listeria* spp. and other potential human pathogens such as *Yersinia enterocolitica* and *Aeromonas hydrophila*.[92,213]

22.4.3 Environmental Sources of Contamination

Personnel

It is unlikely that personnel contribute significantly as a source of microbial contamination of milk during machine milking, although workers suffering from certain zoonoses, such as Q fever, should not be allowed to participate in the milking process.[27]

Aerial Contamination

Air is also an insignificant contributor to microbial contamination of raw milk. It has been calculated that airborne bacteria account for <5 cfu ml^{-1} of the bacterial load of milk; of these *Bacillus* spores would constitute <1 cfu ml^{-1}.[15,264]

Water

Water used in the production of milk should be of potable quality. Storage tanks should be protected to prevent access by insects, rodents, birds, and other sources of contamination and equipment used to deliver water should be properly cleaned. Problems may arise where untreated water supplies are used to rinse and wash equipment. Such water may contain a diverse array of microorganisms including *Pseudomonas* spp., coliforms, *Bacillus* spp., and numerous other genera.[27] The number of cells contaminating the milk may be small but there is the potential for growth in any residual water remaining on the equipment. Chlorination of the water used in the production of milk is recommended. Concerns about the use of untreated water, and even of mains supplies, have been heightened in recent years by the increased incidence of *Cryptosporidium parvum*. It is known that oocysts of this protozoan can be present in raw milk,[120,136,228] albeit at low incidence rates (<1%), but their source is undetermined. However, it is unlikely that the oocysts can survive commercial pasteurization.[109]

22.4.4 Contamination from Milking and Storage Equipment

Significant contamination of milk can arise from inadequately sanitized surfaces of milking and milk storage equipment. McKinnon et al.[162] demonstrated that the total bacteria count of milk may increase by up to 3×10^3 cfu ml^{-1} due to milking equipment and a further 1.5×10^3 cfu ml^{-1} from the bulk tank. The organisms proliferate in milk residues present in crevices, joints, rubber gaskets, and dead-ends of poorly cleaned milking plants.[252,256] A diversity of bacterial types can be introduced into milk from milk mineral deposits present in milking equipment.[251-256] Arguably, the most important of these are the Gram-negative psychrotrophs, which predominate among the microflora that adhere to stainless steel milk transfer pipelines.[146]

Differences in cleaning regimes and, hence, the level of contamination from farm to farm ensure that considerable variation occurs in the microflora of milking equipment.[61] The only real protection against the introduction of bacteria into the milk supply during milking is adequate sanitation of all the equipment.[32,83] Variations in temperature and cleaning procedures affect the attachment of bacteria to stainless steel surfaces.[34,236] The effectiveness of sanitation depends to a large extent on the design of the plant and on other factors such as the hardness of the water supply, which itself can give rise to deposits on milking equipment.[188]

Farm bulk tanks do not contribute greatly to the bacterial load of raw milk because they are easy to clean and, consequently, have a much lower bacterial content than the milk pipeline.[61] However, ancillary equipment such as agitators, dipsticks, outlet plugs, and cocks can be difficult to clean and may be a possible source of contamination.[27] There is also some speculation that inadequately cleaned bulk tanks can be a source of psychrotrophic spore formers.[163] But by far the most important contribution to microbial load afforded by bulk tanks is potential growth of contaminants during storage.[194] Economics is dictating that milk be collected from farms on alternate days, or even longer in some instances. Thus, at collection part of the milk in the bulk tank may be 48 hours old or more. Whereas most of the surveys conducted indicate that alternate day collection has little effect on the bacteriological quality of bulk tank milk providing it was cooled rapidly to 4°C or below before addition to the tank,[61] the "growth potential" of the raw milk microflora is significantly affected.

The length of the lag phase of growth of the native microflora in farm bulk tank milk stored at 2° to 4°C was about 48 hours[105,175] (Figure 22-1). These data support those of Bockelmann[23] who suggested that the critical time for storage of milk at refrigeration temperatures was between 60 and 72 hours. Thus, milk from alternate day collections arriving at a processing site will contain organisms that are entering the exponential phase of growth, and the amount of time that this milk can be subsequently stored will be adversely affected.[185,186] Further evidence that prolonged cold storage can affect the spoilage potential of contaminating bacteria was obtained by Jaspe et al.[124] These workers compared *Pseudomonas* spp. isolated from milk shortly after milking with those isolated from the same milk samples that had been stored at 7°C for 3 days. The strains from the stored milk grew 10 times faster at 7°C, had 1,000-fold more proteolytic activity and were 280-fold more lipolytic than the strains isolated from the freshly drawn milk. However, during the storage period, the *Pseudomonas* counts in the milk increased by only about 1 log cycle. The microbial load prior to bulk storage can also greatly affect the length of time the milk can be safely held.[87,105] Milk produced under poor hygienic conditions will have a short storage life, even at low temperatures.

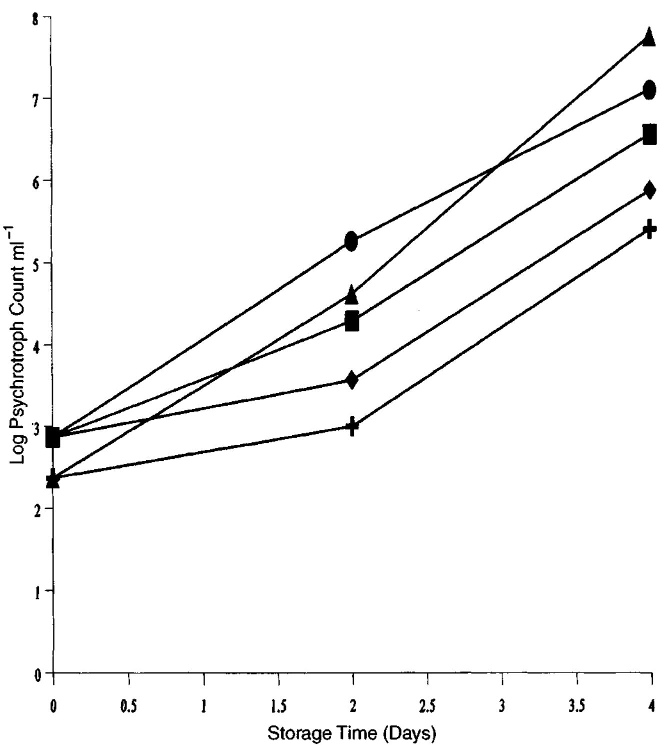

Figure 22-1 Growth of the Natural Microflora of Raw Milk at 2°C (✚; data of Ref. 105); 4°C (◆; data of Ref. 175); 6°C (■; data of Ref. 175); 6°C (▲; data of Ref. 105); and 8°C (●; data of Ref. 175). Counts were obtained on milk agar incubated at 21°C for 25 hours.

Some studies have aimed to determine the relative contributions of contaminants from the udder and from the milking plant. Kurzweil and Busse[135] determined that udder microflora were predominant in low-count milk but, as the microbial load in raw milk increased, a greater proportion of the organisms were derived from the milking equipment. This suggests that high-count milks are the result of inadequate cleaning of milking machines and associated pipelines.

22.4.5 Contamination during Transportation and Storage at the Processing Facility

Dairy equipment used for the collection, transport, and storage of refrigerated raw milk becomes fouled with a milk film, which can support growth of bacteria that consequently become a source of contamination to subsequent batches of milk. Thus, adequate cleaning must be ensured. Washing is usually performed at high temperatures (70°C) but this may exacerbate problems due to heat-induced fouling. Low temperature (45°C) wash procedures can be successfully applied to clean milk collection tankers and storage tanks.[233,234]

Contamination during Transportation

Milk is usually transported in insulated tanks or in tankers equipped with refrigerated storage. The drivers of these vehicles are usually authorized to refuse obviously abnormal milk or milk that is above a certain temperature. Milk may be transferred to larger vehicles for longer journeys. The main causes of increased bacterial count during this stage are contamination due to inadequately cleaned vehicles and growth of bacteria already present in the milk. The latter is obviously dependent on the temperature of the milk and duration of the journey. It has been estimated that a two-fold increase in count is common during transportation from the farm to the processing site because of the proliferation of psychrotrophic bacteria, including coliforms.[143,249]

Bell et al.[12] studied the efficacy of a rapid, ATP bioluminescence-based test for the evaluation of tanker cleanliness. They found that only 63% to 89% of surfaces examined were assessed as free from extraneous contamination. Externally accessible areas such as manways, hoses, and the air elimination vessels were consistently dirtier than the inside of tankers. Critical sites for cleaning have been identified as the air separator, the milk meter, the milk sieve, and the suction hose.[233,234] Factors that contribute to inadequate cleaning include blockage of the cleaning-in-place (CIP) spray system and low water pressure and flow rate. These can lead to build-up of milkstone on the inner surface of the tanker.

Contamination during Storage at the Processing Site

Changes in dairy industry practices, such as the introduction of a 5-day working week and shortages at certain times of year due to the adoption of quota systems, have led to milk being stored for longer times before processing. Because of this, the temperature at which milk is stored becomes critical. It has been recommended that the milk is cooled to, and maintained at, 3°C on receipt at the processing plant before storage.[111] Milk is usually stored in insulated silos prior to processing and can be held under these conditions for 2 to 3 days. The temperature gain in the silos should not exceed 1°C at maximum ambient temperatures over a 24-hour period.[111]

Muir et al.[174] surveyed the bacteriological quality of silo milk at several dairies in southwest Scotland and found the averages for the number of aerobic bacteria and number of psychrotrophic aerobic bacteria to be 1.7×10^5 cfu ml^{-1} and 1.3×10^5 cfu ml^{-1}, respectively. The majority of bacteria present were pseudomonads (70.2%) but Enterobacteriaceae (7.7%), Gram-positive bacteria (6.9%), and other Gram-negative, rod-shaped organisms were also isolated.[176] When the milks were stored for a further 48 hours at 6°C, the psychrotroph count increased by 2 log cycles to 1.3×10^7 cfu ml^{-1}.[175] Psychrotrophic growth patterns were similar whether milks were selected according to their initial total aerobic counts or whether they were stored in large, air-agitated silos or small, paddle-agitated vats.[58] Growth rates were highest during filling of the silos, due possibly to temperature fluctuation, and final bacterial numbers were dependent on initial counts and storage time, with the latter being the most significant factor affecting final quality. Methods to predict growth rates of psychrotrophic microorganisms present in milk have been reviewed by Griffiths.[96]

Following a study of the spoilage of raw and pasteurized milk, Ternström et al.[248] concluded that raw milk was spoiled exclusively by Gram-negative bacteria. Of these, *Pseudomonas fluorescens* biovar I (32.1% of isolates), *P. fragi* (29.6%), *P. lundensis* (19.8%), and *P. fluorescens* biovar III (17.3%) were the most commonly isolated. Other organisms isolated belonged to the Enterobacteriaceae and the genus *Acinetobacter*. *P. fluorescens* biovar I was also the most frequently isolated pseudomonad from raw milk in a study undertaken by Gennari and Dragotto.[88] There is little difference between the types of spoilage associated with bovine milk and ovine and caprine milks.[182,258] Some of the common bacteria isolated from bovine milk and their sources are shown in Table 22-3.

22.4.6 Consequences of Growth of Psychrotrophic Bacteria in Raw Milk

As well as being able to grow rapidly in refrigerated milk, psychrotrophs produce extracellular enzymes that can degrade milk components. Certain of these, proteases and lipases, were alluded to earlier in this chapter. Although the majority of psychro-

Table 22-3 Bacteria Commonly Isolated from Raw Milk

Genus	*Source*
Gram-negative	
Achromobacter (now *Alcaligenes* or *Pseudomonas*)	Soil
Acinetobacter	Soil, water, milking equipment
Aeromonas	Water
Alcaligenes	Soil, water, milking equipment
Alteromonas	Soil, water
Campylobacter	Feces
Chromobacterium	Soil, water
Citrobacter	Water, feces
Enterobacter	Mastitic infections, water, milking equipment
Escherichia	Bedding, mastitic infections, water, milking equipment
Flavobacterium	Soil
Klebsiella	Sawdust bedding, mastitic infections, water, milking equipment
Pseudomonas	Soil, streak canal of udder, water, milking equipment
Salmonella	Feces
Serratia	Soil, water, milking equipment
Yersinia	Feces
Gram-positive	
Arthrobacter	Teat surfaces
Bacillus	Bedding, pasture
Clostridium	Feces, fodder, bedding, teat surface
Corynebacterium	Streak canal of udder
Enterococcus	Feces, water
Lactobacillus	Feces, silage
Listeria	Soil, water, fodder, feces
Microbacterium	Milking equipment
Micrococcus	Teat surface, streak canal of udder, milking equipment
Sarcina	Soil, water
Staphylococcus	Teat surface, streak canal of udder
Streptococcus	Teat surface, streak canal of udder

trophs present in milk are not heat resistant,[194] in many cases the extracellular enzymes that they produce can survive pasteurization (70° to 80°C) and even UHT (120° to 140°C) temperatures.[35,43,46,47,141,194,221] Griffiths et al.[103] showed that both proteases and lipases produced by psychrotrophs, representative of a number of genera, retained 60% to 70% of their activity after heating at 77°C for 17 seconds and about 30% to 40% of their activity remained after UHT treatment at 140°C for 5 seconds. The heat stability of these enzymes is influenced by milk proteins, which exert a stabilizing effect.[134] Not all the psychrotrophs found in milk are capable of synthesizing these enzymes and, even in those that do, the levels produced are affected by many factors, including growth phase, nutrient supply, and environmental conditions, such as temperature, oxygen tension, etc.[72,125,160,194] In addition to proteases and lipases, certain psychrotrophic bacteria produce other extracellular enzymes that affect milk quality such as phospholipase C and glycosidases. The role of these enzymes in the degradation of milk fat was discussed in Section 22.2.2.

22.4.7 Public Health Significance of Raw Milk

Regulations determining the sale of raw milk differ from country to country but, even in jurisdictions requiring mandatory pasteurization of milk, pressure is being placed on the regulatory agencies to relax their restrictions on the availability of this product to the public. This has been driven by the consumers' desire for "natural" foods and the perceived nutritional advantages offered by raw milk. Despite the demands of a vociferous minority, the question remains: Can the safety of raw milk be guaranteed? The answer to that question must undoubtedly be no. There is a vast literature demonstrating the efficacy of pasteurization in reducing milkborne illness and an equally weighty volume of literature documenting illness produced through the consumption of raw milk.[195] In England and Wales during 1985 to 1989, the great majority of outbreaks of milkborne illness were associated with the consumption of raw milk, although it accounted for less than 1% of sales. In Scotland, a similar situation existed until the sale of unpasteurized milk was prohibited in 1983. After this time the incidence of disease associated with liquid milk dropped significantly and was further reduced when legislation was introduced in 1986 to prohibit farm workers from receiving untreated milk as part of their wages (Figure 22-2).[30] The higher number of cases observed in England and Wales may simply reflect differences in population levels. The decrease in cases in England and Wales in 1988 may have been due to an increase in vigilance within the industry following an outbreak of salmonellosis linked to infant formula in 1985, which involved 62 cases and one death. This had severe repercussions for the company that produced the formula and resulted in the Dairy Trade Federation formulating guidelines for the hygienic production of milk products.

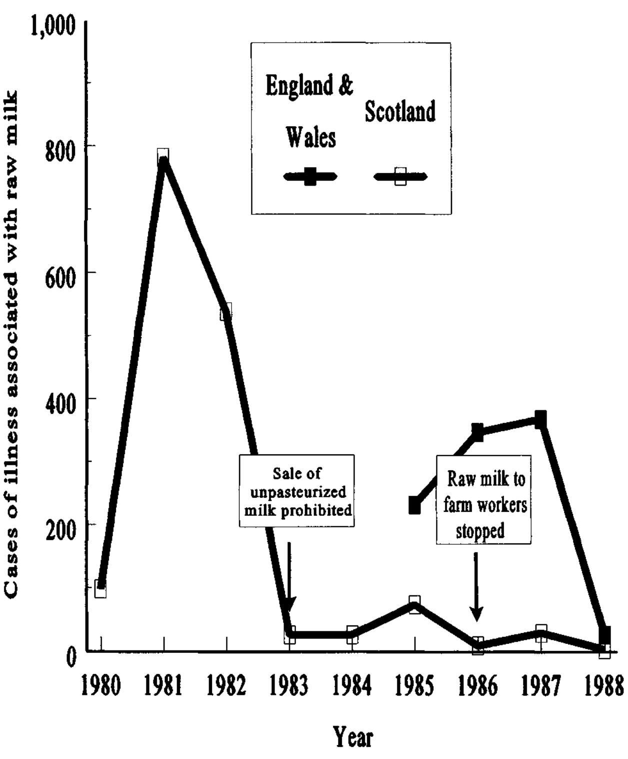

Figure 22-2 Effect of Regulatory Changes on the Incidence of Milkborne Illness in the UK. *Source:* Data from R. Burt and S. Wellsteed, Food Safety and Legislation in the Dairy Industry, *Journal of the Society of Dairy Technology*, Vol. 44, pp. 80–86, 1991.

Further evidence to indicate the hazard associated with consumption of raw milk was produced during a study of foodborne infections conducted in Ontario between 1979 and 1985.[245] Cases of salmonellosis, campylobacteriosis, and yersiniosis were more prevalent in rural areas, and it was concluded that raw milk played an important role in these infections.

Another index of the dynamic nature of milkborne illness is the changes observed in the etiological agents with time. In the middle of the 20th century, the main illnesses associated with the consumption of milk were brucellosis and tuberculosis. These have been eradicated as milkborne illnesses in developed countries, mainly through herd certification programs, the installation of refrigerated bulk tanks for collection of milk on farms, and the introduction of pasteurization. The majority of present-day milkborne illnesses are attributable to *Salmonella* spp., *Campylobacter* spp., and *Listeria monocytogenes* among others and are associated with the consumption of raw milk or pasteurized milk that has either received an inadequate heat treatment or has been contaminated after heating. These epidemiological changes have been brought about by the adoption of new milk production, processing, and distribution practices. Other factors, for example, the changing characteristics of microorganisms and demographic changes such as the ageing population and increase in numbers of immunocompromised individuals, will ensure that this dynamism will continue.[71]

The important pathogens present in raw milk have recently been reviewed in a publication of the International Dairy Federation.[123] Several surveys have been conducted, worldwide, to determine the incidence of pathogens in raw milk. The results of some of the more recent surveys are summarized in Table 22-4. What is obvious is that traditional indices of the microbiological quality of milk, such as aerobic plate counts, cannot be relied upon as a guarantee of the safety of the milk. Pathogens can be isolated from low count milk produced under hygienic conditions.[56,232]

As well as the more common pathogens associated with raw milk, recent attention has focused on the potential of raw milk for the transmission of other organisms. For example, Farrell and Marth[80] have suggested that raw milk may be a vehicle for the transmission of *Borrelia burgdorferi*, the agent responsible for Lyme disease. It has been shown that the organism can survive for at least 46 days in milk stored at 5°C.[81] Also, *Mycobacterium paratubercu-*

Table 22-4 Incidence of Potential Bacterial Pathogens in Raw Milk from Some Surveys Published between 1990 and 1995

Organism	*Incidence in Ontario Bulk Tank Milk*[a] *% Samples +ve*	*Incidence % of Raw Milk +ve*[b] *(mean)*	*References*
Aeromonas hydrophila	—[c]	35.3	122
Campylobacter jejuni	0.46[d]	1.4–12.3 (6.7)	55, 139, 207
Clostridium perfringens	—	0–9.3 (4.7)	55,172
Listeria monocytogenes	2.84	0–15.6 (6.9)	55, 82, 110, 122, 170, 171, 183, 207
Salmonella spp.	0.17	0.1–8.9 (3.1)	55, 183, 203, 207
Staphylococcus aureus	—	62	55
Verotoxigenic *Escherichia coli*	0.81		
Yersinia enterocolitica	—	15.1–36.0 (24.5)	55, 107, 140, 207

[d] *Campylobacter* spp.

losis, suspected to be the etiological agent of Crohn's disease, has been isolated from 11.6% of milks from asymptomatically infected cows.[242] Recently, verocytotoxigenic strains of *Escherichia coli*, particularly the serotype *E. coli* O157:H7, have caused severe food-related outbreaks. Although the primary source appears to be inadequately cooked beef burgers, dairy cattle have been shown to be a major reservoir for infection, and cases linked to the consumption of raw milk have been reported.[63] These have included cases among the families of dairy farmers. *E. coli* O157:H7 is unable to grow in milk at a temperature of 5°C and below and about a 2 log cycle decrease in count is observed after 28 days at this temperature.[271] However, significant growth (1 to 2 log cycles) can occur within 4 days when the milk is stored at 8°C. The organism grows more slowly in unpasteurized than pasteurized milk, presumably because of the antagonistic effect of the native flora and the antimicrobial activity of raw milk.

It is not only bacterial contamination of milk that causes concern. There has been a number of large outbreaks of cryptosporidiosis, an illness produced by the protozoan *Cryptosporidium parvum* (see Chapter 51). Whereas these have mainly been waterborne, there is substantial epidemiological evidence to implicate raw milk as a vehicle.[136] However, a survey of over 100 raw milk samples from Ontario failed to detect *Cryptosporidium* oocysts (Laberge and Griffiths, unpublished results).

22.5 NATURAL ANTIMICROBIAL COMPOUNDS IN RAW MILK

Raw milk is known to contain several antimicrobial compounds. The role of many of these is to confer a degree of protection on neonates of the species from which the milk was obtained and to protect the mammary gland itself from infection. However, these compounds can also play a role in the preservation of milk.

22.5.1 Lactoperoxidase

Arguably, the most extensively studied of the antimicrobial systems found in milk is lactoperoxidase. This enzyme catalyses the oxidation of thiocyanate, in the presence of hydrogen peroxide, to give an intermediary oxidation product, hypothiocyanite, which has antibacterial activities due to oxidation of sulfhydryl groups of proteins and structural damage to the cytoplasmic membrane of bacteria.[272] Thiocyanate is present in a wide variety of animal tissues and secretions, including milk, and the hydrogen peroxide can be generated endogenously by the addition of H_2O_2-forming bacteria such as lactobacilli and lactococci, by the oxidation of ascorbic acid, or by the oxidation of glucose by glucose oxidase.

The lactoperoxidase system (LP-S) inhibits many bacterial species, including milkborne spoilage and pathogenic microorganisms. Its bactericidal action against Gram-negative bacteria, including pseudomonads,[21] has been used to extend the storage life of refrigerated, bulk tank milk.[20] While it has not gained widespread use in developed countries, there are reports on its application in Third World countries. Lactoperoxidase also exerts an inhibitory effect on Gram-negative pathogens, such as *Aeromonas hydrophila*,[214] *Campylobacter jejuni*,[24] *E. coli*,[66,204] including *E. coli* O157:H7,[78] *Salmonella* spp.,[66,199,204] and *Yersinia enterocolitica*.[79] Despite the fact that its effects on Gram-positive bacteria are mainly bacteriostatic, LP-S is useful for the control of the growth of *Listeria monocytogenes*[19,54,64,70,86,130,227] and *Staphylococcus aureus*[130] in milk. The inhibition produced by the LP-S is affected by the metabolic status of the organism, the growth medium, and environmental factors such as pH and temperature. Several methods by which bacteria can be resistant to the effects of LP-S have also been described.[272]

22.5.2 Lactoferrin

Lactoferrin (Lf) is an iron-binding glycoprotein found in milk, which inhibits the growth of many bacteria by its ability to chelate iron.[142] As well as the inhibition caused by its ability to sequester iron, iron-free Lf (apo-Lf) can exert a bactericidal effect through direct interaction with bacterial cell surfaces.[7] The antibacterial properties of apo-Lf are unaffected by pasteurization but are lost upon UHT treatment of milk.[189] The antibacterial effect of Lf has been shown to increase when the glycoprotein is hydrolyzed by heat at acidic pH[211] or by pepsin digestion.[13,260] The inhibition of microbial growth produced by this hydrolyzed product, known as lactoferricin, is not mediated by iron chelation.[211] Lactoferricin is active against a wide variety of organisms, including members of the Enterobacteriaceae, pseudomonads, *Bacillus* spp., and *L. monocytogenes*.[14,128,269] The practical significance of lactoferricin is uncertain.

22.5.3 Lysozyme

Lysozyme is a bacteriolytic enzyme, present in raw milk, that hydrolyzes mucopolysaccharides in bacterial cell walls.[36] The enzyme is capable of surviving HTST pasteurization.[94] Lysozyme is mainly active against Gram-positive bacteria and has been used for the control of late-blowing of cheese by *Clostridium tyrobutyricum*.[33] However, in the presence of chelating agents such as EDTA, lysozyme can exert a significant inhibitory effect on some Gram-negative bacteria.[190,202] The addition of hen egg lysozyme to milk did not have a significant influence on the shelf life achieved,[101] and Stadhouders et al.[230] reported that lysozyme was only effective when spore populations in milk were low (about 3 spores 10 ml^{-1}). However, milk lysozyme may be more effective as an antimicrobial agent than the enzyme from egg.

22.5.4 Immunoglobulins

Bovine milk, especially colostrum, is relatively rich in immunoglobulins and use has been made of this richness through the concept of "passive immunotherapy."[191] Immunoglobulins isolated from bovine milk have been found to reduce incidence of infection by *E. coli*[244] and rotavirus.[67,116] Indeed, raw milk contains an antiviral compound, identified as IgG,[243] which is very effective against rotavirus. It remains to be seen whether there are significant differences between growth rates of pathogens in raw milks containing immunoglobulins directed at the organism of concern and growth rates in raw milks that are free of such antibodies.

22.6 COMPETITIVE EFFECTS BETWEEN MICROORGANISMS FOUND IN MILK

The inhibitory effects of lactic acid bacteria on growth of competing microflora are well documented, and the addition of these organisms to raw milk to increase shelf life prior to processing is an accepted dairy industry practice.[35] The inhibitory effect is mediated through a combination of reduced pH, production of organic acids, and the synthesis of antimicrobial compounds (bacteriocins) by the lactic acid bacteria. However, the most important factor for controlling the growth of psychrotrophs in milk by the addition of lactic acid bacteria seems to be acid production.[98] This technique can only be used for the extension of storage life of milks used for the manufacture of fermented dairy products; therefore, it will not be considered further.

There have been reports that the growth of *Listeria monocytogenes* is influenced by the presence of Gram-negative psychrotrophs such as *Pseudomonas* spp.,[154] *Flavobacterium* spp.,[76] and *Yersinia enterocolitica*.[29] The growth of *L. monocytogenes* was accelerated in media that had previously supported growth of pseudomonads; the effect was mediated through the production of proteases by the pseudomonad.[154] However, when *L. monocytogenes* was grown in the presence of *P. fluorescens* and other Gram-negative psychrotrophs, no such synergistic effects were observed,[74,75,77] presumably due to the fact that *L. monocytogenes* could reach significant levels before the production of proteases by the Gram-negative psychrotrophs. It was concluded that *L. monocytogenes* was an effective competitor with the common microflora of milk when grown at low temperatures. Farrag and Marth[76] determined that the growth of *L. monocytogenes* was enhanced in the presence of *Flavobacterium lutescens* but was inhibited by another species of *Flavobacterium*. *Yersinia enterocolitica* also inhibited *L. monocytogenes* during growth at 10° and 22°C in mixed culture, but the inhibitory effect was not apparent at 4°C.[29]

Mesophilic strains of *Bacillus* spp. (mainly *B. subtilis* and *B. licheniformis*) produce factors that are antagonistic to the growth of psychrotrophic strains of the same genus.[241] The significance of these interactions is not entirely clear but they may influence the incidence and growth of psychrotrophic strains in the farm environment.

22.7 OTHER METHODS FOR PROLONGING THE STORAGE LIFE OF RAW MILK

22.7.1 The Need To Prolong the Storage Life of Milk

As stated earlier in this chapter, because of changes in management practices at the farm and at the dairies, raw milks are being subjected to longer storage times before processing. This has led to the development of methods to extend the storage life of raw milks. The two methods that have gained greatest acceptance both involve the use of temperature: either heating or cooling.

22.7.2 Thermization

Thermization is a heat treatment, usually in the range 60° to 65°C for 10 seconds, designed to reduce the psychrotroph count to levels that will allow storage of the milk at 4°C for 3 to 5 days. The process can be carried out on the farm or at the processing site. In a study of the effects of heat treatment at sub-pasteurization temperatures on raw milk, Griffiths et al.[104] found that the temperature of thermization had a greater influence on storage life of raw milk at 4°C than the holding time. The ability to extend the storage life beyond 3 days was also determined by the initial psychrotroph count of the milk. If this count exceeded 1 × 10^4 cfu ml^{-1}, then to achieve a 3-day storage life required a combination of thermization and storage at 2°C.

22.7.3 Deep Cooling

Many workers have studied low temperature storage as a means of controlling the growth of psychrotrophs in raw milk.[35] By decreasing the storage temperature for raw milk from 6° to 2°C, a 2-day increase in storage life was observed for milk that had an initial psychrotroph count less than 1 × 10^4 cfu ml^{-1}.[105] The microflora of the milk "deep cooled" to 2°C was different from that stored at 6°C, with a greater preponderance of pseudomonads and lower proportion of Enterobacteriaceae in the milks stored at the lower temperature. Mathematical models have been produced that describe the growth of the microflora of milk as a function of temperature.[96]

22.7.4 Addition of CO_2

The growth of bacteria in milk can be inhibited by the addition of CO_2 at concentrations between 20 and 30 mM.[206] The addition of the gas caused a pH drop in the milk from between 6.59 and 6.7 to 6.2 and, following storage of the milks for 6 days at 7°C, there were significant differences in bacteria present in the treated and untreated milk (Table 22-5). The anaerobic count did not increase in the CO_2-treated milk. Similar extensions of storage life were obtained by King and Mabbitt[132] in an earlier study. There are concerns that CO_2 addition to milk can increase the heat resistance of spores present in milk.[106] As well as the effects on microbial growth, CO_2 may influence enzyme production by psychrotrophs. Rowe[209] found that lipase synthesis was inhibited more than the growth of *P. fluorescens* after

Table 22-5 Effect of CO_2 Addition at Concentrations between 20 to 30 mM on the Microflora of Milk Stored at 7°C for 6 Days

Population	*With CO_2 (cfu ml^{-1})*	*Without CO_2 (cfu ml^{-1})*
Aerobes	2.4 × 10^5	3.6 × 10^8
Coliforms	2.0 × 10^2	7.0 × 10^3
Facultative and obligate anaerobes	2.3 × 10^3	4.6 × 10^5

Next Page

the addition of 30 mM CO_2 to milk. The interest in the preservative effects of CO_2 in milk is continuing with its proposed use to extend the shelf life of pasteurized milk.

22.8 PROCESSING OF RAW MILK

22.8.1 The Need for Pasteurization

In many countries pasteurization (or equivalent heat treatment) is required before milk can be sold. The range of milk products available has also increased to meet consumers demands for products lower in fat. An increasing proportion of the fluid milk supply is homogenized as more milk is sold in cartons or pouches. Each of these steps has consequences for the microflora of milk. The effect of processing on the microbiology of milk will be discussed in the following sections.

22.8.2 Pasteurized Milk and Cream

Before milk is pasteurized it often undergoes cream separation. This is achieved by passing milk, warmed to 40° to 50°C, through a centrifugal separator. The milk temperature may vary depending on the equipment and plant policy. The procedure may remove some bacterial cells, especially those present in large clumps, but there is no evidence that the distribution of bacteria differs between the cream layer and the aqueous phase.[173]

Whole milk and cream are usually homogenized to disperse fat globules and, in the case of half and single creams, to increase viscosity. The homogenization step may help to break down clumps of cells. It also involves warming of the milk, so it is recommended that this step be carried out prior to any heat treatment of the product. Homogenization also makes the fat more susceptible to the action of lipases present in the milk. Lanciotti et al.[138] demonstrated that continuous homogenization at pressures between 400 and 2,000 bar resulted in an initial decrease in viable numbers of *Y. enterocolitica* and *L. monocytogenes* in milk, but the damage to the cells was reversible. However, the viability of vegetative cells of *B. subtilis* continued to decrease with time of storage of the milk at 3° to 4°C after homogenization, probably because the organism was not well adapted to growth at low temperatures. The natural microflora of the milk did not decrease upon subsequent refrigerated storage of the homogenized milk.

Flavor defects in milk and other dairy products can arise from four sources: (1) microbial growth in the milk prior to pasteurization, (2) activity of thermoresistant enzymes, (3) growth of thermoresistant organisms following pasteurization, and (4) post-pasteurization contamination.

Microbial Growth Prior to Pasteurization

Some of the factors affecting bacterial growth in raw milk have been addressed in previous sections of this chapter. It is generally recognized that bacterial counts of more than 1×10^6 cfu ml^{-1} are required before microbiologically related flavor defects are detected in milk.[35,194] However, the exact number of psychrotrophs necessary to produce off-flavors varies between species and is affected by growth rate and by the ability of the organism to produce extracellular enzymes that can degrade milk components.[46] Generally, in countries adopting good husbandry practices, the quality of the raw milk will rarely impinge on the quality of the final product. Ravanis and Lewis[201] determined that pasteurized milk with microbiological shelf lives of between 29 and 36 days at 4°C could be produced from raw milk that had been held for 9 days also at 4°C. At that point, the psychrotroph count in the raw milk was about 1.4×10^7 cfu ml^{-1}. Maximum shelf lives were obtained when the raw milk had been stored for 3 to 4 days but not when the milk was pasteurized after only 1 day of storage. They attributed this to the LP-S being maximally active under the former storage conditions. However, a major drawback to this study was that no organoleptic assessment of the milk was performed.

Activity of Thermoresistant Enzymes

The importance of the thermoresistance of the extracellular enzymes produced by many psychrotrophs has been addressed in several reviews.[35,43,46,72,141,160,194,231] The reader is referred to these for detailed information.

Growth of Thermoresistant Organisms in Milk Following Pasteurization

Pasteurization will destroy the majority of organisms associated with raw milk. Typical D- and z-values for some organisms commonly isolated from milk are shown in Table 22-6. There may be variations in the survival depending on the type of milk being pasteurized. Fat exerts a protective effect on Gram-negative bacteria and *L. monocytogenes.* The effect is more pronounced in sheep's milk than either cows' or goats' milk[151] but the protection was not sufficient to allow survival after current HTST pasteurization protocols. Nevertheless, there are

Table 22-6 Heat Resistance of Microorganisms Associated with Milk

Organism	D-value at 71°C in Milk (seconds)	z-Value (°C)
Pseudomonas fluorescens	0.001	4.4
P. fragi	0.26–0.32	6.9–7.6
Salmonella typhimurium	0.22	5.3
Campylobacter jejuni	0.02[a]	5.1
Yersinia enterocolitica	0.35–1.17[a]	5.1
Listeria monocytogenes	0.9	6.3

some bacteria that are capable of surviving pasteurization and growing in the heat-treated milk. Arguably, the most important of these are members of the genus *Bacillus*. The most frequently isolated species of *Bacillus* from pasteurized milk are *B. cereus* and *B. cereus*-group, *B. licheniformis*, *B. circulans*, *B. firmus*, and *B. subtilis*.[51,102,127,163,246] Of these, *B. cereus* and related species can grow at temperatures as low as 6°C[62,102] while other species, most notably *B. circulans*, can grow at 2°C.[102]

Psychrotrophic strains of *Bacillus* spp. have been isolated from about 70% of samples of pasteurized milk[102,163] and are capable of producing off-flavors in milk.[164] Of greater concern, however, may be the large percentage of toxigenic, psychrotrophic strains of *B. cereus* that can be isolated from milk and that have been shown to be capable of producing enterotoxin during growth in refrigerated milk.[41,95,266] Growth of these bacteria in creams was always associated with obvious spoilage but, in flavored desserts, spoilage was not always evident before high numbers of *B. cereus*, with consequent toxin production, were reached.[240] Other *Bacillus* spp., including *B. licheniformis*, *B. subtilis*, and *B. pumilus*, all of which have been isolated from pasteurized milk, have been implicated in foodborne illness.[97]

There has been much debate as to the source of the *Bacillus* spp. isolated from pasteurized milk. Crielly et al.[51] suggested that post-pasteurization contamination may not be the most important source of the organism, but their study did not involve typing of isolates. Evidence is accumulating, based on fatty acid profiling, biotyping, and genotyping, that *B. cereus* strains isolated from pasteurized milks are specific to the plant where the milk was processed[217] and that raw milk is the main source of these spore formers.[148] A study on the presence of *B. cereus* in a dairy plant showed that the number of spores in the milk decreased at each stage from the raw milk in the tanker, through storage, pasteurization, and packaging.[5] This decrease was explained by *B. cereus* spores adhering to surfaces throughout the processing chain. Thus, niches may occur in dairy plants downstream of the pasteurizer where *B. cereus* would proliferate almost unchecked and contribute to post-pasteurization contamination of the product.

The importance of thermoresistant psychrotrophs will increase as the move toward extended shelf life products gains momentum. In these heat-treated, aseptically packaged products, shelf life is mainly limited by *Bacillus* spp.[22,52] Cromie[52] studied milk processed at between 72° and 88°C and concluded that, when milk was stored at 3°C, the milk heat treated at 72°C had the longest shelf life but the difference was not as great when milk was stored at 7°C. The faster growth in milk processed at the higher temperatures could be due to spore activation, destruction of natural milk antimicrobial systems, or reduced competition from other bacteria. When extended shelf life milk was produced by heat treatments at between 100° and 145°C, *Bacillus* spp. were isolated from milk processed at and below 132°C but no organisms were isolated from milk heated at 134°C and above.[22]

Although no definite link has been verified, there is evidence that *Mycobacterium paratuberculosis* is linked to Crohn's disease. There is now substantial evidence to suggest that this organism can survive pasteurization.[38,92,241] Recent work has cast doubt on these findings as, although *M. paratuberculosis* was able to survive temperatures between 65° and 76°C for up to 30 minutes when the heat treatment was performed in test tubes, the bacterium was effectively killed in raw milk heated at 72°C for 15 seconds in a laboratory-scale pasteurizer.[229] Further studies of the heat resistance of *M. paratuberculosis* in milk indicate that the levels of this bacterium that might occur in raw milk will not survive pasteurization.[131]

Post-Pasteurization Contamination

Although the Gram-negative, psychrotrophic bacteria present in raw milk do not survive pasteurization, the majority of studies on the microbiological quality of pasteurized milk and cream have reported the appearance of these organisms,[35,50,194] with *Pseudomonas* spp. being the most commonly isolated. Thus, it would appear that the shelf life of pasteurized products is limited by post-pasteurization contamination.

Milks with short shelf lives (<5 days at 4° to 6°C) contain almost entirely *Pseudomonas* spp. (90.7% of isolates), while milks with shelf lives >10 days have a higher proportion of other types of microorganisms (*Pseudomonas* spp. accounting for 68% of isolates).[100]

A variety of sources of contamination exist in the processing plant.[194] Personnel and air probably contribute little to the contamination of pasteurized fluid milk products. The normal microflora of air is dominated by Gram-positive bacteria, yeasts, and molds that do not grow well in milk at refrigeration temperatures. Vatne and Castberg[267] report the manufacture of good quality milk in dairies where the air contained aerobic counts as high as 2.8×10^3 cfu m^{-3}, although they recommend that the count should not exceed 1.5×10^2 cfu m^{-3} and the yeast and mold count should be less than 50 cfu m^{-3}. However, Ren and Frank,[205] following a study of the air quality of four fluid milk processing plants, concluded that personnel were a major source of biological aerosol in the dairy plant. This highlights the need for strict control, especially in packaging areas where there may be a safety concern.

With the concern raised by *L. monocytogenes* in dairy products, numerous surveys have been conducted into environmental sources for this organism in fluid milk plants.[224] In general, wet areas of the plants, such as conveyers, floors, drains, and case washers, were significantly more contaminated than dry areas. Although environmental samples were more frequently *Listeria*-positive than equipment swabs, environmental contamination (eg, floors, drains, air) did not necessarily mean that equipment would be contaminated within the same plant.[198] The plants were more likely to be contaminated if they were in close proximity to dairy farms.[197]

Contaminants are able to enter the pasteurized milk at any stage after the heat treatment. This contamination can even occur in the regeneration, cooling sections, and related pipelines of the pasteurizer itself.[4,222] This is especially true during extended operation of the pasteurizers beyond 8 to 9 hours.[144] After this period of time, bacterial numbers in pasteurized milk often rose exponentially and could reach $>1 \times 10^6$ cfu ml^{-1}. The increase was not seen in samples from the holding tube but occurred in milk sampled from the cooling side of the regeneration section. The rate of bacterial contamination was influenced by the raw milk quality which, in turn, was related to temperature and flow characteristics of the raw milk in prepasteurization balance tanks. These bacteria were mainly thermoduric streptococci that did not necessarily influence the shelf life of the product because of their inability to grow at low temperatures.[25] Potentially, the most dangerous form of contamination contributed by the heat exchanger is adulteration of the pasteurized product by raw milk through leakage in the regeneration section because of corrosion.[16] Improper operation, allowing inadequate heat treatments, is also a serious cause of contamination of the final product, which has resulted in outbreaks of milkborne illness.[194]

Contamination of the heat-treated milk can occur downstream of the heat exchanger. This contamination can arise from milk pipelines and holding tanks. The role of airborne contaminants in the contamination of pasteurized milk has been the subject of much debate[194] but may be an important contributor especially during the emptying of storage tanks. A more likely cause of post-pasteurization contamination is shedding of bacteria from biofilms formed on gaskets in pasteurized milk pipelines. Electron microscopy has been used to show that biofilms can develop on the sides of gaskets, despite operation of clean-in-place systems.[8] It is well accepted that sanitizer efficacy is greatly reduced against bacteria growing in biofilms.[169] However, other workers, using radiolabeled bacteria, concluded that milk inhibited adherence of the bacterial strains studied to steel, rubber, and glass. They suggested that intrinsic bacterial adherence did not contribute significantly to the contamination of dairy equipment.[237]

Other factors may contribute to survival of organisms on gaskets. For example, Pfeifer and Kessler[192] provided evidence that the heat resistance of *B. cereus* spores increases when they are present in an enclosed space between a silicone rubber seal and a stainless steel surface. This would be the case with gaskets. They postulate that the increase in heat resistance is due to the reduced water activity of the environment.

There is substantial evidence that the filling operation has the greatest influence on the potential shelf life of pasteurized milk.[99,168,218] Low levels of bacteria (10 to 500 psychrotrophs $liter^{-1}$) can be introduced into the product at this stage, which can have a profound effect on shelf life.[100] Continuing improvements to the design of fillers have resulted in dramatic effects on the keeping quality of milk.[219] The influence of aseptic packaging of milk on the expected shelf life was amply demonstrated by Schmidt et al.[216] who demonstrated that this milk could be kept for about 48 days when stored at 3°C. Pasteurized milk is not usually aseptically packaged, whereas the procedure is necessary for UHT milks to maintain "commercial sterility."

The packaging material can also have an influence on the shelf life of pasteurized milk either by direct contamination of the product by organisms on the material, or indirectly by allowing bacteria to penetrate into the product.[150]

22.8.3 UHT Products

Milk that has undergone UHT treatment is "commercially sterile," although certain spore formers, especially species of thermophilic *Bacillus*, are able to survive the process. However, they generally do not limit the shelf life of the product because they are unable to grow much below about 40°C. It is accepted that the major cause of failure in UHT products is due to packaging problems associated with the aseptic filling techniques. A comprehensive review of UHT processing has been published.[31]

Recent problems have been encountered in Europe because of the ability of certain highly heat-resistant spores of mesophilic *Bacillus* spp. to survive the UHT process and grow during testing under the new European Union (EU) Regulation 92/46.[108,145] Although they do not compromise shelf life or safety, they cause "false" failures under the regulations.

Prior growth of Gram-negative psychrotrophs in raw milk can have a significant effect on the sensory acceptance of UHT milk because of the ability to produce thermostable extracellular enzymes. The psychrotrophic count in raw milk was strongly correlated ($r = 0.95$) with the extent of proteolysis in stored UHT milks.[45] Correlations between the level of proteolysis and bitter flavors in stored UHT milk were high when the milk was stored at 30°C ($r = 0.90$) and at 40°C ($r = 0.92$), but not when the UHT milk was stored at 20°C ($r = -0.23$). Length and temperature of storage had a greater effect on the sensory quality, and hence shelf life, of the UHT milk than the psychrotrophic count of the raw milk.

22.8.4 Condensed/Evaporated Milk

Sweetened Condensed Milk

With the technology currently employed to produce sweetened condensed milk, microbiological defects are relatively uncommon. The problems that do arise are almost invariably due to contamination of the milk following forewarming. The most common microbiological problems are gas formation from the growth of the yeast, *Torulopsis*, or, more rarely, growth of coliforms. The defect usually appears slowly because of the slow growth rate of the organisms at the high sugar concentration of the product and results in blowing of the container.[180] Many species of bacteria, particularly micrococci and *Bacillus* spp., can cause thickening in condensed milk of low sugar content. Mold growth and coagulated casein can also be observed on the surface of opened cans that have been stored for long periods of time. Both *Penicillium* and *Aspergillus* spp. have been implicated. The thickening and mold growth are generally the result of contamination from the plant environment and can be controlled by storing the product at lower temperatures, as well as improving plant sanitation.[180]

Evaporated Milk

Evaporated milks are produced by an aseptic canning process and, hence, are commercially sterile. Problems are encountered only when heat treatments are inadequate or when organisms are introduced into the product through leaks in the hermetic seal of the can.[180] The most common defects are caused by *Bacillus* spp., and *B. stearothermophilus*, *B. coagulans*, *B. licheniformis*, *B. subtilis*, and *B. macerans* have all been isolated from evaporated milk with flat sour spoilage.[129] When cans are opened by the consumer, contamination is invariably introduced and the product becomes perishable.

22.8.5 Dried Milks

The emphasis on the production of dried milk powders has turned toward the manufacture of products with specific properties and to minimizing treatments in order to optimize the nutritional value of the end product. These trends have increased the need for reliable microbiological control. The low water activity of milk powders precludes the growth of microorganisms and, generally, bacterial numbers in powdered milk decrease during storage.[149] However, the microbiological quality of the raw milk used to manufacture dried milk can have a bearing on its properties, especially solubility, but only when the count in the raw milk is greater than 2×10^6 cfu ml^{-1}.[173]

As much of the milk powder manufactured is used for infant formula, particular attention must be focused on safety. Mettler[166] reviewed the requirements for pathogen control during the production of spray-dried milk powder and identified the following five critical rules: (1) prevention of pathogen entry into the plant, (2) prevention of growth in the event of pathogen entry, (3) pasteurization to reduce pathogens to a safe level, (4) prevention of post-pasteurization contamination, and (5) knowledge of the pathogen status of staff, premises, materials, equipment, and product. Far from being only applicable to the manufacture of powdered milk, attention to these points is crucial for the production of all nonfermented dairy products.

Despite the good record of the industry, outbreaks of foodborne illness associated with the consumption of milk powders have been documented.[166] Of the 24 outbreaks cited by Mettler,[166] 20 were due to *Salmonella* spp., 3 were caused by staphylococcal enterotoxin, and 1 was associated with *Clostridium perfringens*. Salmonellae can survive spray drying, and there is evidence that contamination by both *Salmonella* spp. and *Staphylococcus aureus* may take place during manufacture.[149] In response to this, the microbiological standards for milk powders are continually being tightened.

Concern has been raised about the presence of *B. cereus* in dried milk products, especially infant foods.[11,51] Spores can survive in powders for at least 6 months[173] and both Holmes et al.[118] and Kramer and Gilbert[133] have cited outbreaks of *Bacillus*-related foodborne illness associated with milk powder and infant formula. This concern may be heightened by results indicating that about 50% of samples of infant formulae were contaminated with *B. cereus*[11] and that these organisms could grow rapidly in reconstituted milks stored at ambient temperatures.[11,51] The temperature of reconstitution also played a role in the rate of growth during storage, with growth being most rapid in powders reconstituted at 45°C.[11]

22.8.6 Butter

Although butter contains not less than 80% fat, not all of the water is present as discrete droplets expected in an ideal water-in-oil emulsion; some exist as minute continuous channels in which microorganisms can proliferate.[10] In such a compartmentalized food, microbial growth is proportional to the availability of nutrients and the radius of the water droplets.[268] The main cause of spoilage of butter is lipolytic rancidity. In cold-stored, sweet-cream butter, only organisms that can survive low temperatures and high salt concentrations are found with micrococci generally predominating. However, *Pseudomonas* spp. may be introduced from wash water and cause a surface taint.[178]

There have been outbreaks of illness caused by staphylococcal enterotoxin in butter[17] and *Staphylococcus intermedius* was identified as the causative agent in one outbreak where butter was the vehicle of transmission. *Listeria monocytogenes* survived and grew in butter made in a small, home-style churn.[184] This may not be indicative of the organism's ability to survive the commercial buttermaking process where the moisture droplets in the butter may be smaller.

The trend toward low-fat (or light) butter is disturbing from a microbiological standpoint. Lanciotti et al.[137] observed that the yeast, *Yarrowia lipolytica*, and the bacteria, *Enterococcus faecium* and *Bacillus polymyxa*, were the organisms most commonly isolated from commercial packages of light butter. They also isolated *Bacillus firmus*, *B. laterosporus*, and a yeast, *Cryptococcus albidus*. Of greater concern is the ability of *L. monocytogenes* and *Yersinia enterocolitica* to grow in this product. *Listeria monocytogenes* displayed a higher growth potential than *Yersinia*, possibly due to it being less affected by space and nutrient limitations in this compartmentalized food.[137]

22.8.7 Ice Cream

The microbiology of ice cream has been reviewed by Rothwell.[208] He divided the factors that affect the microbiological quality of ice cream into three components: (1) the quality of the raw materials, (2) the efficiency of processing, and (3) hygienic conditions under which the ice cream is produced. Of the various materials that can be used to produce ice cream, many can contribute to the quality and safety of the final product. However, proper handling and storage will eliminate the majority of problems.

Ice cream mix is a highly viscous product. Concern has been expressed that laminar flow conditions are set up during HTST pasteurization, resulting in underheating of the product, even at the higher pasteurization temperatures usually used to process this product.[89] That laminar flow is achieved during HTST pasteurization of ice cream mix was confirmed by Davidson et al.[53] In addition, it has been found that the heat resistance of *Listeria monocytogenes* is increased by common stabilizers used in ice cream mix, such as guar gum and carrageenin.[119] Thus, particular attention should be paid to ensure that the mix receives an adequate heat treatment.

As well as the use of high quality raw materials and provision of an adequate pasteurization process, proper attention must be paid to the cleanliness and sanitation of the processing plant, plant personnel, and dispensing equipment. The latter is a particular cause for concern for soft-serve ice cream, which is sold from a special dispensing freezer. These dispensers must be properly cleaned and disinfected at frequent intervals and problems due to the presence of *L. monocytogenes* in these products are still evident. Post-pasteurization contamination of ice cream products by *Listeria* can occur via aerosol formation even at subzero temperatures.[90]

Many pathogens, including *Listeria monocytogenes* and *Yersinia enterocolitica*, can survive freezing.[69,261] In recent years, ice cream has acted as a vehicle for the transmission of listeriosis, salmonellosis, and *Staphylococcal* enterotoxin poisoning.[208] A recent large outbreak of salmonellosis was attributed to ice cream that had become contaminated during transportation of ice cream mix in a truck previously used to carry raw liquid egg. This incident highlights the need for vigilance during all aspects of production of not only ice cream, but all food products. *Bacillus cereus* has also been isolated from a large number of ice cream samples (48% in one survey[1]) and outbreaks attributed to the presence of *B. cereus* in ice cream have been reported.

22.9 OTHER METHODS OF PASTEURIZATION OF MILK

22.9.1 The Need for Alternatives to Heat Treatment

Because of possible nutritional losses and organoleptic changes associated with heat pasteurization, along with high energy costs, there has been much interest in the development of nonthermal pasteurization methods. A number of these are under investigation, though none have replaced HTST treatments to date.

22.9.2 Microfiltration

Using ceramic membranes with pore sizes of 1.4 µm, a system has been developed that allows the sanitary cross-flow filtration of milk. This method, termed microfiltration, has been shown to reduce bacterial numbers in nonfat milk by up to 3 log cycles[68,263] and *Listeria innocua* in milk by about 2 log cycles.[152] Milk treated by combination of a microfiltration process with a minimum HTST pasteurization (about 72°C for 16 seconds) is currently sold in Canada. The thermal pasteurization step is still a statutory requirement and cannot be omitted. Before microfiltration the milk is skimmed and the fat is heat treated separately before recombination with the microfiltered, HTST pasteurized skim to produce a milk with the desired fat concentration. The products have an extended shelf life of at least 32 days at 4°C, and an improvement in organoleptic quality is claimed.

22.9.3 Bactofugation

Microorganisms can be removed from milk by centrifugation in a process called bactofugation. The method is claimed to be effective at removing bacterial spores[226] but it can be plagued by problems with recontamination. An extended shelf-life milk produced by combining bactofugation and HTST pasteurization is on sale in Canada. It has an expected shelf life of at least 30 days at 4°C.

22.9.4 Irradiation and Microwave Treatment

Sadoun et al.[210] proposed that a low-dose irradiation of milk was possible without affecting organoleptic or nutritional properties. A treatment of 0.25 kGy at room temperature doubled the shelf life of pasteurized milk. Irradiation at 0.5 kGy produced a 2 log cycle reduction in bacterial count of raw milk, but the changes in the sensory properties of the milk were such that the treatment had little effect on storage life.

Microwave heating has also been shown to have limited application for milk.[112]

22.9.5 Ultrasound

The antimicrobial effects of ultrasound (or sonication) have been known for over a century but there has been limited work carried out on its application in the food industry. Ultrasound mainly works by cavitation, the production of bubbles or cavities in a liquid.[215] Cavitation can be either stable, where the bubbles remain intact and damage cells by shear forces, or it can be transient, causing large pressures to be produced when the bubbles collapse.[65] These large pressures disrupt cell-wall structures, resulting in irreparable damage to the cell. Early work conducted on the pasteurization of milk by ultrasound produced disappointing results but bacterial cells become more sensitive to subsequent heat treatments after sonication.[65,212] This effect may be utilized to reduce the temperatures required to adequately pasteurize milk products.

22.9.6 High Hydrostatic Pressure

The availability of commercial equipment for high-pressure processing of foods has revived interest in this technique as an alternative to thermal pasteurization.[165] Pressure causes protein denaturation and disrupts the structural integrity of cells.[65,179] However, the problem posed by recovery of cells sublethally damaged during hydrostatic pressure treatments must be overcome. The answer may lie in the development of combined treatments as proposed for sonication. Spores may also survive high pressure but the treatment seems to activate them and pressure-germinated cells could be subsequently eliminated by an alternative treatment.[65]

22.9.7 High Voltage Electric Pulses

Use of high voltage electric pulses (HVEP) is one of the most promising techniques currently under investigation for the nonthermal pasteurization of milk.[200,223] Qin et al.[200] cite research that used HVEP to successfully pasteurize raw milk with a peak electric field of 40 kV cm^{-1} and 20 pulses each of 2 μsec duration. This represents a significant reduction in cost over thermal pasteurization techniques.[117] Reversed polarity of the pulse appears to be necessary for optimal antimicrobial effects[117] and there are preliminary reports that this technology is also lethal to spores.[157]

22.10 THE FUTURE

Many large outbreaks of disease transmitted by milk or milk products have occurred in recent years, but these have invariably been due to the consumption of raw milk, milk that had received an inadequate heat treatment, or milk that had been contaminated after pasteurization. Nevertheless, both producers and processors have made significant strides to improve the quality and safety of dairy products but the amazing adaptability of microbial populations means that the challenge to maintain standards will not lessen. Indeed, as new technologies are adopted, different problems will ultimately emerge. To deal with potential threats to the microbiological safety and quality of milk products, the production, processing, and retailing components of the industry must work together to develop integrated quality management and hazard analysis critical control point (HACCP) schemes. It is only by concerted action that the high standards set by the dairy industry in the past can be maintained.

Fermented Milk Products

Michael Teuber

CHAPTER CONTENTS

23.1 Historical introduction
23.2 The substrate milk
23.3 Sources of microorganisms used in dairy fermentations
  23.3.1 Taxonomy and identification
  23.3.2 Brief microbiological characterization of starter microorganisms and important contaminant microbes
  23.3.3 Biochemistry and genetics of starter cultures
  23.3.4 Propagation and preservation of starter cultures
  23.3.5 Commercially available starter cultures
  23.3.6 Quality standards for dairy starter cultures
  23.3.7 Natural (artisanal) starter cultures
23.4 Fermented milk products
  23.4.1 Outline of the microbiological, biochemical, and hygienic complexity
  23.4.2 Sour milk products
  23.4.3 Cheese
23.5 The bacteriophage problem in dairy fermentation
  23.5.1 The extent of the problem
  23.5.2 The *Lactococcus*-specific bacteriophages
23.6 Fermented dairy products containing "probiotic" microorganisms
23.7 The microbiological safety of fermented dairy products
  23.7.1 Safety of sour milk products
  23.7.2 Safety of cheese
  23.7.3 Biogenic amines in fermented dairy products and cheeses
  23.7.4 Antibiotic-resistant bacteria in cheese
23.8 Concluding remarks

23.1 HISTORICAL INTRODUCTION

Agriculture and pastoralism formed the basis for the neolithic revolution about 7,000 years BC, ie, for the transition of a mostly nomadic way of living of hunters and gatherers into a sedentary life. The domestication of farm animals was initially a method of keeping live meat (protein) reserves. Evidence from excavated bone remains from settlements of about 5,000 BC indicate an increasing number of adult female animals. This provides the first circumstantial evidence that sheep, goats, and cattle were also kept for milking. We have no physical evidence for fermented milk products from prehistoric times.[54] The invention of writing about 3,200 BC by the Sumerians started with bookkeeping documents of agricultural products and commodities. These documents already contained signs for dairy products such as milk, butter, fat, cheese, and yogurt obtained from goats, sheep, and cows.[128] The assumptions on how these early dairy products were made by spontaneous fermentation follows.[40,135]

Acknowledgments. I would like to thank Ulrike Wollert for the tedious typing work, and specifically Dr. Barbara Lund for her expert editing of my manuscript and her patience.

dried cheese

Butter oil and dried cheeses can be kept for years because they are microbiologically stable as long as they are kept in dry conditions (Table 23-1).

Later literary documents from Greece (eg, Homer's *Iliad* and *Odyssey*) and Palestine (*Old Testament* of the *Bible*) contain evidence of the existence of sour milk and cheeses. The fermentation of milk into such products seems to be an ancient heritage of human culture. This was only possible because the milk provided quite specific conditions for lactic acid bacteria to cause fermentation sufficiently rapidly to limit the growth of spoilage bacteria (eg, bacilli, pseudomonads, or clostridia). However, it was only in 1856 that Louis Pasteur realized that the lactic fermentation of milk was a microbial process.[104] It then took only a few decades to isolate and describe the main bacterial species responsible for lactic fermentations, ie, the mesophilic and thermophilic lactic acid bacteria with coccoid and rod-shaped morphologies. The first of these bacteria obtained in pure culture was *Bacterium lactis*, now called *Lactococcus lactis*.[84] The first bacterial starter cultures for dairy fermentation isolated from spontaneously fermented milk and cheese were available around 1900 in Denmark, Germany, and the United States. These starter cultures were provided as liquid cultures in milk. After World War II, freeze drying was employed to prepare cultures that were stable in vacuum-sealed containers for many months and could be shipped at ambient temperatures to all parts of the world. Deep-frozen, concentrated cultures which, like freeze-dried concentrated cultures, can be applied for direct inoculation of fermentation tanks developed about 20 years ago. The microbiological development of dairy starter cultures culminated in the application of the principles of genetic engineering to lactic acid bacteria within the last 10 years.[48] Genetically modified lactic acid bacteria (eg, with modified phage resistance, bacteriocin production, proteolysis, lactose fermentation) are ready to be applied in practice as soon as the legal, environmental, and health issues are resolved. The most recent development is the application of lactic acid bacteria as "probiotics" and antigen-delivery systems for vaccination purposes.[144]

Table 23-1 Estimated Keeping Times of Dairy Products at Ambient Temperatures (20° to 30°C)[135]

Keeping Time	*Milk and Its Protein Fraction*	*Fat Fraction*
½ day	raw milk	sweet cream
1 day	boiled milk	—
1 week	sour milk	sour cream
2 weeks	sour curd/fresh cheese	butter
2–3 weeks	soft cheese	—
1–2 years	hard cheese	—
Several years	dried cheese	butter oil

The scope of this chapter is to summarize the microbiological principles of modern dairy fermentations with brief references to the underlying biochemical, genetic, ecological, technological, and hygienic aspects.

23.2 THE SUBSTRATE MILK[136]

Milk of several animal species is used for fermentations into sour milk and cheese (Table 23-2). The main biochemical components necessary for the lactic acid bacteria are lactose as a carbon and energy source, the casein fraction as a nitrogen source, and citrate as a substrate for diacetyl production. The free amino acid fraction of cow's milk, for example, is too low to provide for cell densities higher than 10^7 cfu ml^{-1} for nonproteolytic bacteria.

Specific indigenous antimicrobials in milk, including the lactoperoxidase/thiocyanate/hydrogen peroxide systems, lysozyme, and iron-binding lactoferrin, probably inhibit Gram-negative, facultative bacteria more than the Gram-positive anaerobic or microaerophilic lactic acid bacteria. However, these systems are only active in raw milk because they are denatured by pasteurization.

During milking, contamination of raw milk with microbes derives from the environment (skin, udder, feces, air, fodder, equipment) and excretion with milk if the animal suffers from latent or acute mastitis or other infective diseases.[131] In the dairy there is a risk of further pre- and post-pasteurization contamination. Therefore, the production of microbio-

logically safe milk for fermented dairy products requires careful control of every single production step. Pasteurized milk or milk reconstituted from milk powder (produced from pasteurized milk by spray or drum drying) are now the preferred substrates worldwide for dairy fermentations. The use of raw milk for the production of fermented milk products is declining steadily, but continues in some countries for reasons of tradition. It should be emphasized that the microbiological quality of raw milk is variable and unpredictable. Irrespective of traditions, pasteurized milk together with well characterized starter cultures has proven to eliminate non–spore-forming pathogenic bacteria prior to dairy fermentations.

23.3 SOURCES OF MICROORGANISMS USED IN DAIRY FERMENTATIONS

Analysis of fermented dairy products offered on the market shows that they are developed from products that were originally fermented spontaneously and are now manufactured by using well characterized starter cultures. These cultures have been isolated and developed from the traditional spontaneously fermented products in the course of the last hundred years.[18]

23.3.1 Taxonomy and Identification

Following the initial isolation of starter culture components from spontaneously fermented products like sour cream, cheeses, and yogurt by pioneers (Weigmann, Storch, and Cohn), Orla-Jensen[102] was the first bacteriologist to propose a clear differentiation scheme for lactic acid bacteria on the basis of morphology (rod/coccus), sensitivity to oxygen, presence of catalase, gas formation (hetero- versus homofermentative bacteria), and response to growth temperature (mesophilic versus thermophilic bacteria). However, these properties were not sufficient to differentiate clearly all occurring lactic acid bacteria, propionibacteria, bifidobacteria, brevibacteria, and closely related forms as well as yeasts and molds found in and on fermented dairy products. It was due to modern methods of biochemistry, chemotaxonomy (cell wall composition, fatty acid and protein profiles), and molecular biology (DNA-DNA hybridization, ribosomal RNA sequences) that a very clear picture of the evolutionary relations and finally a clear taxonomy evolved.[120] The main organisms recognized as important in starter cultures are shown in Table 23-3. Only a limited number of bacterial, yeast, and mold genera are important for dairy starter cultures. Some of the species used are only found in dairy products, which means that they have been selected and cultivated empirically by the dairy manufacturers in the course of hundreds or thousands of years of practical use.

The classical whey culture (ie, whey remaining from the previous fermentation was inoculated into the milk for the next production) that was therefore a very successful method of propagating the microflora adapted to the corresponding product and environment without knowing the exact composition. The most important consequence of the modern clear-cut taxonomy is the fact that the microorganisms used in starter cultures are very well characterized and differentiated from related pathogenic or undesirable microorganisms (eg, from *Listeria*, enterococci, hemolytic streptococci, hemolytic staphylococci).[125] Figure 23-1 shows an evolutionary tree based on 16S ribosomal RNA sequences providing clear-cut positions for the bacteria used in dairy fermentations as compiled in Table 23-3. It should be mentioned that specific nucleotide probes are available to identify pathogenic bacteria and starter bacteria by PCR techniques or colony hybridization.[73,80]

Table 23-3 Main Microorganisms Used in Starter Cultures for Fermented Dairy Products

Species	*Normal Habitat*	*Function*
Brevibacterium linens	cheese surface	1. surface ripening 2. competitive displacement of other microbes
Lactobacillus helveticus	Swiss cheese, yogurt	1. thermophilic lactic fermentation 2. slow protein degradation during ripening
Lactococcus lactis subsp. *lactis* subsp. *cremoris* subsp. *diacetylactis*	sour milk cheddar cheese Gouda cheese fresh cheese	1. mesophilic lactic fermentation 2. diacetyl production 3. slow proteolysis
Leuconostoc lactis	sour milk and butter cultures	aroma formation (diacetyl)
Propionibacterium spp.	Swiss cheese	1. propionic fermentation 2. eye formation
Streptococcus thermophilus	yogurt culture	lactic fermentation
Candida kefir	kefir	alcoholic fermentation
Penicillium camemberti	Camembert cheese	1. surface ripening 2. competitive displacement of undesired molds
Penicillium roqueforti	Roquefort cheese bread	aroma formation (methylketones)
Bifidobacterium spp.	intestine	"probiotic" action
Lactobacillus acidophilus	intestine, vagina	"probiotic" action

23.3.2 Brief Microbiological Characterization of Starter Microorganisms and Important Contaminant Microbes (Figure 23-2)[109,117,132,147]

Bifidobacterium[7]

These bacteria are typical of the human intestinal tract and are strictly anaerobes belonging to the family of *Actinomycetes*. Bifidobacteria colonize the originally sterile intestines of breast-fed infants within the first week of life, resulting in up to 10^{11} colony-forming units (cfu) per g of feces. The low pH (about 4) of the infant's stools results from a typical heterofermentative lactic acid fermentation, during which fructose-6-phosphate is converted by a specific phosphoketolase into erythrose-4-phosphate and acetyl-phosphate, because the normal pathway through the pentose-phosphate cycle is blocked due to the unavailability of the glucose-6-phosphate dehydrogenase. Thus, two molecules of fructose-6 P give rise to two molecules of L(+) lactic acid and three molecules of acetic acid. Bifidobacteria can be also found in high numbers in the intestines of adults. The acids produced by bifidobacteria are thought to play an important role in the control of putrefactive microorganisms in the bowel. Outside the intestines the bifidobacteria die quickly in the presence of traces of atmospheric oxygen. They grow well under anaerobic conditions in milk but the flavor changes thus produced are largely undesirable (predominantly acetic acid!). Research into the pos-

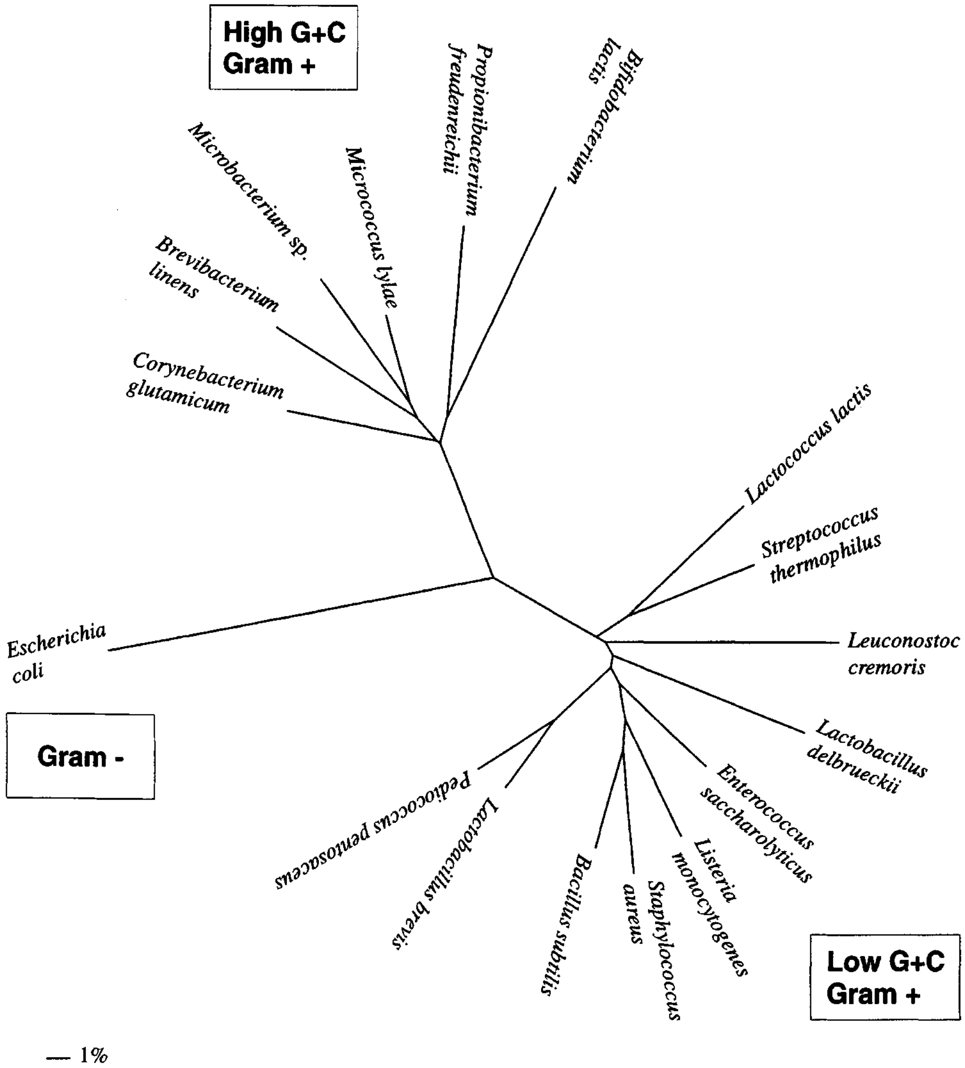

Figure 23-1 Phylogenetic Tree of Desirable and Undesirable Gram-Positive Bacteria Important for Milk Fermentations. The tree was constructed by the neighbor-joining technique on the basis of 16S ribosomal RNA sequences available in public databanks (eg, GenEMBL) according to the principle of Schleifer and Ludwig.[120] Courtesy of G. Dasen, Eidgenossische Technische Hochschule, Zurich, Switzerland.

sibility of introducing bifidobacteria into the intestinal flora by means of fermented dairy products shows inconclusive results (Section 23.6).

Brevibacterium linens

These bacteria are responsible for the surface-ripening of red-smear and yellow-smear cheeses. *B. linens* is Gram-positive, rod-shaped, and obligately aerobic and belongs to the high G+C branch of bacteria (Figure 23-1). The piquant aroma produced by *B. linens* is due to its strongly proteolytic and lipolytic activities.

Coryneform Bacteria[140]

Gram-positive strictly aerobic bacteria like *Arthrobacter/Micrococcus* and *Microbacterium* species from the high G+C branch are part of cheese surface microflora and contribute to ripening in a similar way to *Brevibacterium linens.* A full description of their function still needs considerable research efforts.

Enterococcus[32]

Bacteria in this genus include the species *E. faecalis* and *E. faecium,* which are important to the

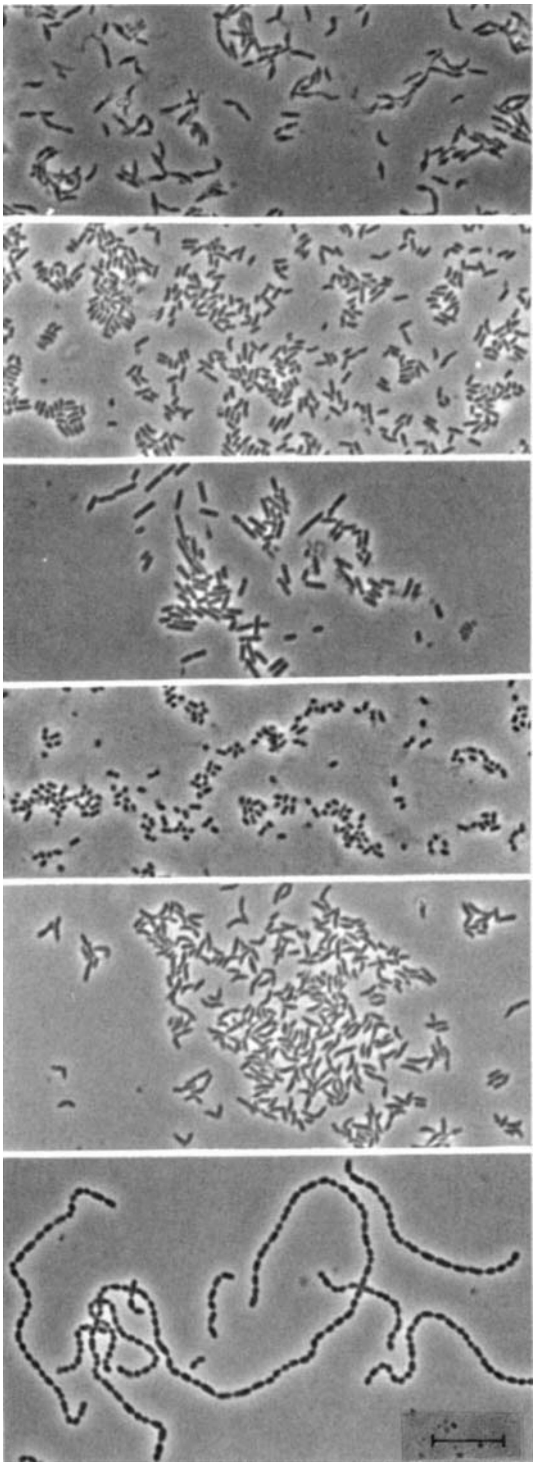

Figure 23-2 Phase Contrast Photomicrograph of Important Bacteria for Dairy Fermentations, from Top to Bottom: *Bifidobacterium bifidum, Brevibacterium linens, Lactobacillus helveticus, Lactococcus lactis, Propionibacterium shermannii, Streptococcus thermophilus.* Courtesy of B. Kollöffel and U. Schuler-Schmid, Eidgenössische Technische Hochschule, Zurich, Switzerland.

dairy industry. Originating in intestinal tracts of many animals, these bacteria are relatively thermoresistant, ie, they can survive pasteurization conditions in small numbers ($D_{65°C}$ values around 2 minutes, z-values around 7 to 8).[91] Subsequently, under suitable growth conditions, they can multiply to high counts. Because they are highly osmo-tolerant, they may cause problems especially in concentrated dairy products such as evaporated milk and whey concentrates, as well as in cheese. These bacteria are found regularly in raw milk, but only under nonhygienic manufacturing conditions are they found in cheese from pasteurized milk. Enterococci are the causative agents of certain infectious diseases, including urinary tract inflammation or endocarditis.[63] Food poisoning due to enterococci has not yet been conclusively documented, as experiments with volunteers have not shown any poisoning symptoms. For certain very highly salted fresh and rennet-coagulated cheese, the use of starter cultures with enterococci has been suggested. However, as the manufacture of these products is possible using unquestionably nonpathogenic lactic acid bacteria, the use of enterococci as components of starter cultures should be rejected, particularly if they carry transmissible antibiotic-resistant genes (Section 23.7.4). Recently, cultures of *E. faecium* have been promoted as a probiotic component of animal feeds or even yogurt for human consumption, aiming at a possible colonization of the individual's intestine to act as an inhibitor of growth of pathogenic enterobacteria such as *Salmonella.* As with the colonization of human intestines by bifidobacteria, the effectiveness of the probiotic use of *E. faecium* is very difficult to confirm experimentally (see Section 23.6).

Lactic Acid Bacteria[132]

These are Gram-positive, rod- or coccoid-shaped bacteria whose main metabolic product resulting from breakdown of sugars is lactic acid. According to this definition, this group also contains a number of undesirable or pathogenic organisms such as enterococci, hemolytic streptococci, and pneumococci. In food technology, the term identifies those organisms that are used in various food- or feed-fermentation processes. According to modern developments in bacterial taxonomy, all technologically useful lactic acid bacteria are classified within the genera *Streptococcus, Lactobacillus, Lactococcus, Leuconostoc,* and *Pediococcus.* In practical aspects of the fermentation processes, the technological properties play a more important role for the differentiation and determination of these bacteria than the molecular biology approach. All lactic bacteria have an essentially anaerobic metabolism, although they may not be inhibited by the presence of atmospheric oxygen. Thus, they are occasionally described as being microaerophilic. Technologically, the following are some important differentiation characteristics:

1. **Homofermentative versus heterofermentative metabolism (lactic acid metabolism).** Homofermentative lactic acid bacteria used in dairy technology include all *Lactococcus* species, *Streptococcus thermophilus*, *Lactobacillus helveticus*, *Lactobacillus delbrueckii* subsp. *bulgaricus* and subsp. *lactis*, *Lactobacillus casei*, *Lactobacillus acidophilus*, and *Pediococcus* species. Heterofermentative lactic acid bacteria in the physiological sense include all *Leuconostoc* species, *Lactobacillus kefir*, *Lactobacillus brevis*, *Lactobacillus fermentum*, and *Bifidobacterium bifidum*.
2. **Temperature response.** Thermophilic lactic acid bacteria include *Streptococcus thermophilus*, *Lactobacillus delbrueckii* subsp. *bulgaricus* and subsp. *lactis*, and *Lactobacillus helveticus*. Mesophiles include all *Lactococcus*, *Leuconostoc* and *Pediococcus* species, *Lactobacillus casei*, and *Lactobacillus kefir*.
3. **Salt tolerance.** This is especially high (over 6.5% NaCl) for some *Enterococcus* and *Pediococcus* species, moderate for some *Lactobacillus* species (eg, *L. casei*), and low for all *Lactococcus* species.
4. **Production of lactic acid stereoisomers.** These are predominantly (>95%) L(+) lactate in all *Lactococcus* and *Streptococcus* species, *Lactobacillus casei*, and *Bifidobacterium bifidum*, predominantly D(–) lactate in *Lactobacillus delbrueckii* subsp. *lactis*, and *Leuconostoc*. A mixture of L(+) and D(–) lactate (racemate) is produced by *Lactobacillus acidophilus*, *Lactobacillus helveticus*, and *Pediococcus*.

The earlier differentiation of the lactobacilli into thermobacteria (*Lactobacillus delbrueckii, lactis, helveticus, acidophilus*), streptobacteria (*L. casei, plantarum, curvatus*) and betabacteria (*L. fermentum, brevis, buchneri*) has been largely abandoned today.

Lactic acid bacteria usually have requirements for complex nutrient media; their needs include amino acids, vitamins, trace elements such as manganese, and other growth factors. Suitable media for their propagation include milk, tomato juice, and others. Often they are very sensitive to their own product, lactic acid. If proper pH control is used in the production of commercial starter cultures, unusually high bacterial numbers (about 10^{10} ml^{-1}) can be obtained.

Lactobacillus acidophilus is a lactic acid bacterium whose natural habitat is the intestine and vagina of warm-blooded animals. Occasionally, it may be added to fermented dairy products for its proposed positive effect on the intestinal flora of the consumers. This, however, is very difficult or impossible to prove scientifically (Section 23.6). Presently, these bacteria are considered to be harmless to human health.

Lactobacillus brevis is a heterofermentative lactic acid bacterium, found especially in sour dough (in breadmaking). It is undesirable in fermented dairy products because of uncontrollable gas production.

Lactobacillus bulgaricus, as found in the traditional literature, is now regarded as a subspecies of *Lactobacillus delbrueckii*: *L. delbrueckii* subsp. *bulgaricus*. It is a thermophilic and homofermentative lactic acid bacterium that forms a main component of the traditional yogurt culture.

Lactobacillus casei subsp. *casei* is a homofermentative and mesophilic lactic acid bacterium present particularly in hard cheeses and in cheeses made from raw milk.

Lactobacillus helveticus is a thermophilic, homofermentative lactic acid bacterium that is a principal component of the microflora in hard cheeses.

Lactobacillus kefir is a heterofermentative lactic acid bacterium in kefir grains, to a certain extent related to *Lactobacillus brevis*.

Lactobacillus lactis, in modern taxonomy regarded as a subspecies of *L. delbrueckii*, is a thermophilic, homofermentative lactic acid bacterium. It is a component of starter cultures for hard cheeses.

Lactococcus[134] is a genus of mesophilic lactic acid streptococci (formerly *Streptococcus*) that are present in many starter cultures for cheese, cultured milk, sour cream, and fresh cheese. It includes the subspecies *L. lactis* subsp. *lactis* (used for acid production), *L. lactis* subsp. *cremoris* (used for acid production), and *L. lactis* subsp. *lactis* biovar *diacetylactis* (used for production of the aroma compound diacetyl). The *cremoris* subspecies is associated only with milk and milk products, some of the *lactis* strains have also been found in plant materials. However, these wild strains have different properties from those of strains predominating in milk and dairy products. The strains used in the dairy industry today can be considered as "domesticated" because they have been used for their particular purpose for hundreds of years and have been cultivated unknowingly for a long time. From the health standpoint they are considered to be completely harmless bacteria. *Lactococcus* is homofermentative and produces only L(+) lactic acid. The proteolytic system required for growth in milk is specific for β-casein in many strains. Some strains of *Lactococcus* produce an antibiotic polypeptide, nisin, that is mainly effective against Gram-positive bacteria (eg, clostridia). Many technological functions of *Lactococcus* are coded on plasmids; this explains why today *Lactococcus* is a favorite research subject of molecular engineering.[48]

The *Leuconostoc* group of heterofermentative lactic acid bacteria decompose lactose to D(–) lactic acid. *L. cremoris* is used in butter culture for the formation of aroma (diacetyl).[26]

Propionic Acid Bacteria[20]

These bacteria are used in production of some cheese types for propionic acid fermentation. *Propionibacterium* induces conversion of lactic acid to propionic acid under anaerobic conditions. This biochemically very complex reaction results in conversion of three molecules of lactic acid into two molecules of propionic acid, one molecule of acetic acid, one molecule of carbon dioxide, and one molecule of water. The propionic acid bacteria can be found in the rumen microflora and intestinal tract of ruminants. They belong to the *Actinobacteria* class and are not strictly anaerobic but microaerotolerant. The carbon dioxide produced during the propionic fermentation causes the eye formation in Swiss cheese. The maximum amount of propionic acid in such cheeses is about 100 mMol kg^{-1} cheese. The optimum reaction temperature is well above 20°C, corresponding to the conditions where it occurs naturally (rumen and intestines of ruminants). For controlled eye formation in Emmental cheese, temperatures of about 24°C are used. This process takes about 12 weeks. Propionic acid bacteria are sensitive to nitrate. Thus, in cheeses in which propionic fermentation is desired, late-blowing through growth of butyric acid bacteria cannot be controlled by the addition of nitrate. Propionic acid bacteria are available commercially as a liquid starter culture.

Penicillium roqueforti[118]

This is a blue mold used for the production of Roquefort, Gorgonzola, Stilton, and other blue cheese varieties. It is found widely in nature, eg, on moldy grain or bread; however, these wild strains are not suitable as starter cultures for cheese manufacture. The strains used by the dairy industry have been in use for several decades and are well characterized both microbiologically and technologically. Starter cultures, traditionally produced on sterilized bread and washed off with physiological saline solution, are available in both liquid and dried form. They contain about 10^9–10^{10} conidia g^{-1} of preparation and are added to the cheese milk at the beginning of the coagulation period. To ensure mold growth in the inner areas of the cheese, the cheese loaf must be pierced to allow the entry of the required oxygen. *P. roqueforti* strains are proteolytic and lipolytic and the resulting characteristic aroma of the blue cheese is correspondingly complex. The main factors appear to be the degradation products of fatty acid breakdown, including methyl ketones such as 2-heptanone, 2-nonanone, 2-pentanone, and 2-undecanone, as well as the corresponding alcohols 2-pentanol, 2-heptanol, and 2-nonanol, together with the usual products of protein degradation. Because *P. roqueforti* can easily be confused with undesirable contaminant molds, the culture production requires stringent and continuous control. The strains used by the dairy industry produce in the cheese up to 7 ppm of roquefortin and a few strains up to 15 ppm mycophenolic acid.[38] These metabolites are considered to be of no significance to public health in the amounts ingested. Carcinogenic mycotoxins have not been detected in these cheeses. Animal experiments carried out by the German Center for Cancer Research have not established any risk associated with the consumption of blue cheese.[103]

Penicillium camemberti[118]

This is used for the surface-ripening of Camembert, Brie, Handkäse, and other cheeses. The nomenclature of the *Penicillia* has undergone some confusing changes in recent years. From the standpoint of practical use the situation can be summarized as follows: All "white molds" important for dairy technology belong to the original species *P. camemberti.* These old strains are characterized by a gray to bluish appearance of their well-developed mycelia. Conversely, strains with pure white mycelium were first classified as *P. candidum* and later reclassified as *P. caseicolum*. Thus, the gray-blue mold should be denoted as *P. camemberti*, the pure white mold as *P. caseicolum*, while the name *P. candidum* is still often used correctly as a synonym for *P. caseicolum*. Production of starter cultures of *P. camemberti* takes about 4 weeks using a semi-solid nutrient medium. The conidia developed in the process are washed with physiological saline solution, and adjusted to concentrations of about 10^9–10^{10} germination-ready conidia per g preparation for commercial use. Such cultures can be kept in a refrigerator for several months. Freeze-dried conidia are also available now; however, the proportion of nonviable conidia in the powdered form is much higher (up to 90%) than in the liquid preparations of equal concentration. If regular production of uniform quality culture combined with prompt delivery service can be provided by the manufacturer, it is easier to utilize the liquid culture because there are no problems in dissolving it in the cheese milk. Being an aerobic organism, *P. camemberti* develops only on the cheese surface. The mycelium shows a rapid growth about 5 days after the cheese production. A uniform growth of the inoculum mold inhibits any undesirable contaminating molds. Preparations known as "anti-*Mucor* cultures" show this property in the laboratory but the effect can seldom be seen under practical conditions. All 62 *P. camemberti* strains tested that are currently being used for cheese production have been shown to produce cyclopiazonic acid, a substance with hepato- and neurotoxic effects for rats (the LD_{50} for these animals is between 36–63 mg kg^{-1} body weight). In the normally ripened and handled cheese, the maximal levels of cyclopiazonic acid were 0.3 ppm and the average was about 0.15 ppm.[38] The average consumption of Camembert cheese in the Federal Republic of Germany results in uptake of about 1 ng kg^{-1} body weight. Thus, from the public health standpoint, the consumption of cyclopiazonic acid in Camembert and Brie cheeses is of no concern. Carcinogenic mycotoxins such as aflatoxin, ochratoxin, and sterigmatocystin are not produced.

Recently, submerged fermentation of *P. roqueforti* and *P. camemberti* has been successfully developed instead of solid substrate fermentation of starter culture preparations[11] (Figure 23-3).

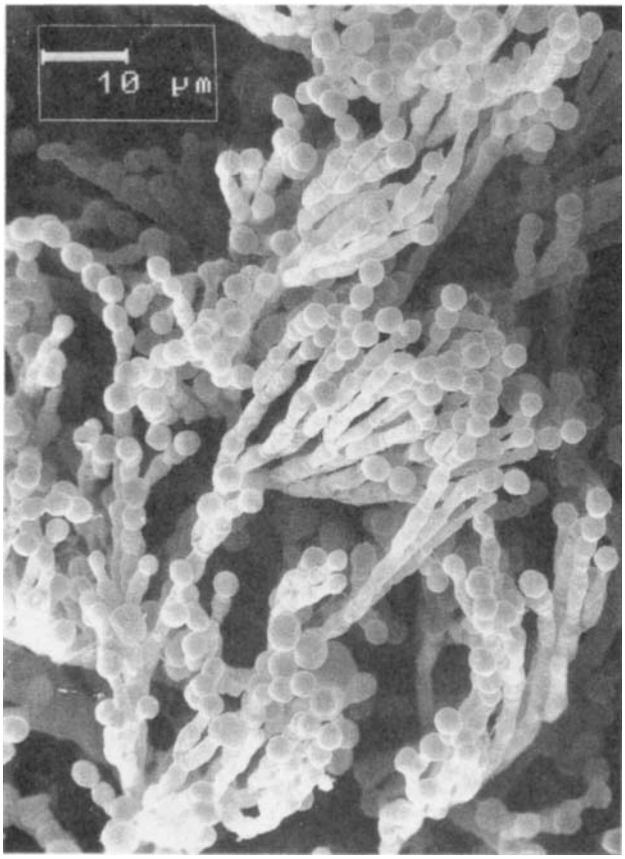

Figure 23-3 Scanning Electron Micrograph of *Penicillium camemberti* Grown in Submerged Fermentation, a New Method To Produce Conidia for Dairy Starter Cultures. Courtesy of H. Neve and W. Bockelmann, Federal Dairy Research Centre, Kiel, Germany.

Staphylococcus aureus

All over the world this bacterium is the most frequent cause of mastitis in cattle, sometimes also in sheep and goats (see Chapters 22 and 47). It may be present in up to 70% of samples of raw milk, in numbers up to 10^2 to 10^5 cfu ml^{-1}.[29,30]

Yeasts

Yeasts are eucaryotic microorganisms belonging to fungi, often regarded as budding fungi. In contrast to most other fungi, yeasts are, as a rule, single-cell organisms that can switch between aerobic and anaerobic metabolism. The importance of yeasts for the dairy industry lies primarily in their acid tolerance and ability to metabolize lactic acid, resulting in spoilage of fermented dairy products. As starter cultures they are used to a limited extent in the manufacture of kefir and in the ripening of red- and yellow-smear cheeses where they cause primary neutralization of the cheese surface enabling the subsequent growth of the smear bacteria (mainly *Brevibacterium linens*).

Raw milk regularly contains various yeasts, including (in order of abundance): *Geotrichum candidum, Trichosporon cutaneum, Candida curvata, Candida famata, Candida globosa, Kluyveromyces marxianus, Candida kefir, Candida lambica, Candida krusei,* and *Hansenula anomala.* During pasteurization, all these are inactivated.[35]

The shelf life of fresh cheese, quark, and cottage cheese is limited primarily by the presence of yeasts. One yeast cell in a 250 g package can multiply in the cold storage conditions to more than 1 million cells

g^{-1} product within 2 to 3 weeks. Because yeasts can produce a noticeable off-flavor (defect: "yeasty" or "fermented-fruity") with 10^4–10^6 cells g^{-1} (depending on the species), packages with such high yeast counts are considered spoiled in the sense of the Food Act. In addition to the sensory effects, the yeast fermentation leads to production of alcohol and carbon dioxide and to swelling or blowing of the containers. Yeasts do not produce any mycotoxins, so that the consumption of yeast-contaminated products is not dangerous from the health standpoint. The most abundant yeasts in fresh cheese (in order of quantity) are *Geotrichum candidum, Kluyveromyces marxianus, Candida valida, Candida kefir, Pichia membranaefaciens, Candida lipolytica,* and *Candida famata.* The presence of yeasts in fresh cheese, quark, and similar products can be avoided only by ensuring yeast-free fermentation followed by recontamination-free aseptic packaging, or by pasteurization and aseptic packaging after fermentation.[36]

Lactose-fermenting yeasts, especially *Candida kefir* and *Kluyveromyces marxianus* subsp. *marxianus,* are natural components of the classical kefir grains. In addition, lactose-negative yeasts such as *Saccharomyces cerevisiae* and *S. unisporus* as well as *Candida holmii* are often present; these can utilize the breakdown products of lactose (glucose and galactose). In classical kefir, these yeasts can produce up to 1% ethanol. The accompanying production of carbon dioxide causes container swelling if unsuitable packaging is used. In a product denoted as "mild kefir" in the Federal Republic of Germany, the lactose-fermenting yeasts may be omitted from the starter culture for this reason.[37]

23.3.3 Biochemistry and Genetics of Starter Cultures

A thorough knowledge of their biochemical pathways and the genetics regulating these pathways is a prerequisite to a controlled application of starter cultures in modern dairy technology. The advance of genetic engineering has lead to an almost complete elucidation of the transformation from lactose to lactic acid by homofermentative bacteria, and to lactic acid, acetic acid, ethanol, and CO_2 in heterofermentative bacteria[68] and characterization of the enzymes involved. Likewise, the mechanisms of the breakdown of casein during milk fermentation and cheese ripening have been investigated in great detail.[72]

The formation of the important aroma compound diacetyl from citrate by specific bacteria (*Leuconostoc* spp., *Lactococcus lactis* subspecies *lactis* biovar *diacetylactis*) is well understood.[57]

The scientific progress is especially evident in the genus *Lactococcus* because most of the technologically important functions are coded for on plasmids, which are more easily accessible to genetic analysis and genetic engineering than enzymes coded for on the bacterial chromosome. Because elaborate reviews are available,[48,134] it suffices to mention the main plasmid-coded traits: lactose transport and metabolism, casein degradation by cell-wall proteases, citrate and oligopeptide transport by specific permeases, bacteriophage protection by restriction/modification and abortive infection, formation of extracellular polysaccharides, bacteriocin production and immunity, insertion (IS) element–dependent recombination and cointegrate formation, antibiotic resistances, heavy metal and UV resistance, conjugal transfer and mobilization of plasmids, and plasmid replication.

Based on small cryptic plasmids, cloning, expression, and shuttle vectors have been developed. Cloning and expression of homologous and heterologous genes as well as secretion of the gene products have been successfully achieved. To become independent of antibiotic-resistant selection markers, food-grade selection markers have been introduced such as the lacF marker present in pNZ1125 used to express the pepN gene (a debittering peptidase with potential for accelerated cheese ripening). However, to the author's knowledge, genetically modified lactic acid bacteria are still not applied in the industry because of safety and legal concerns.

The main biochemical and ecologically important properties of some dairy lactic acid bacteria are listed in Table 23-4. As mentioned earlier, once curd formation by lactic acid fermentation or by action of rennet has taken place, the activity of the coagulum-embedded microorganism can only be manipulated by different temperature regimes, diffusion of salt from the brine into the cheese interior, and by loss of moisture during cheese ripening. In addition to the temperature and salt tolerance data, Table 23-4 lists the important metabolic products and their concentrations in fermented milk. Biochemically important aspects of propionibacteria, bifidobacteria, yeasts, and molds are mentioned in the paragraphs on specific products.

23.3.4 Propagation and Preservation of Starter Cultures[18,119,136]

Starter cultures are needed and applied by the industry producing food and feed as indicated in Table 23-3. Dairy products are almost always made with

Table 23-4 Ecologically Important Properties of Some Dairy Lactic Acid Bacteria

commercial cultures. Because of its advanced state, the manufacture of lactococcal dairy cultures is described, but the principles are the same for all lactic acid bacteria.

Liquid, dried, and frozen starter cultures are in use. Starter cultures must have a high survival rate of microorganims coupled with optimum activity for the desired technological performance, eg, the fermentation of lactose to lactate, controlled proteolysis of casein, and production of aroma compounds like diacetyl. Because the genes for lactose and citrate fermentation as well as for certain proteases are located on plasmids, continuous culture has not been successful because fermentation-defective variants develop easily. In most instances, pasteurized or sterilized skim milk is the basic nutrient medium for the large-scale production of starter cultures because it ensures that only lactococci fully adapted to the complex substrate, milk, will develop. For liquid starter cultures, the basic milk medium may be supplemented with yeast extract, glucose, lactose, and calcium carbonate. To obtain optimum activity and survival, it may be necessary to neutralize the lactic acid that is produced by addition of sodium or ammonium hydroxide. Because many strains of lactic streptococci produce hydrogen peroxide during growth under microaerophilic conditions, it has been beneficial to add catalase to the growth medium, thus leading to cell densities of more than 10^{10} viable units ml^{-1} of culture.

For the preparation of concentrated starters, the media are clarified by proteolytic digestion of skim milk with papain or bacterial enzymes to avoid precipitation of casein in the separator used to collect the lactococcal biomass. The available self-cleaning clarifiers, eg, bactofuges, concentrate the fermentation broth to cell concentrations of about 10^{12} cfu ml^{-1}. These concentrates can either be lyophilized or are preferentially transferred dropwise into liquid nitrogen. The formed pellets are packed in metal cans or cartons and are kept and shipped at −70°C (dry ice). These modern starter preparations allow the direct inoculation of cheese vats, because the bacteria immediately resume logarithmic growth if harvested in the late logarithmic growth phase. This modern technology shifts most of the microbiological work and responsibility from the cheese factory to the starter producer.

The classical liquid starter culture with about 10^9 cfu ml^{-1} and traditional lyophilized cultures containing about 10^9 cfu g^{-1} must be further propagated in the factory. However, lyophilized cultures can be transported easily and kept at ambient temperature for several months. Concentrated lyophilized starters are also suited for direct vat inoculation having a short lag phase, however, before growth is resumed. Direct vat inoculation may have a certain advantage regarding protection against bacteriophages, which are common in the open dairy fermentation systems (see below).

23.3.5 Commercially Available Starter Cultures[18]

(Consult also catalogs of starter culture producers: Texel, Marshall-Miles, Christian Hansen, and Labor Wiesby.)

Several starter culture producers are active in the field of dairy fermentations. In modern dairying, provision of cultures has almost completely switched from "natural" whey cultures to industrially produced ones. The culture industry offers a variety of cultures to the dairy industry. In culture catalogs, the available cultures are divided into the following categories:

1. Mesophilic cultures of lactic acid bacteria
2. Thermophilic cultures of lactic acid bacteria
3. Molds (*P. camemberti, P. roqueforti*)
4. Yeasts (*Geotrichum candidum, Candida, Brettanomyces*, etc.)
5. Special cultures (propionibacteria, *Brevibacterium linens*)
6. Probiotic cultures (bifidobacteria, *Lactobacillus acidophilus, Lactobacillus casei, Lactobacillus casei* subsp. *rhamnosus*, etc.)

The performance of all starter cultures has to be well characterized. For citrate-fermenting mesophilic cultures (*Lactococcus* and *Leuconostoc* species) these characteristics include the time to reach pH 4.5 (about 20 hours), acid and aroma production, gas formation, acidification capacity (maximum pH after 48 hours at 20°C about 4.3 to 4.4), activity of the bulk starter culture (pH value after 6 hours fermentation at 30°C, about 4.8 to 5.15 at 1% inoculation), and recommended maximum cooking temperatures (38° to 39°C). If gas formation has to be slow to guarantee regular eyes, eg, in Gouda cheese, the initial concentration of *Lactococcus lactis* subsp. *lactis* biovar *diacetylactis* and *Leuconostoc* has to be low.

Mesophilic cultures without citrate fermentation should give pH 4.4 within 18 hours, pH 4.15 to 4.25 within 48 hours at 22°C, and pH 4.8 to 5.0 after 6 hours fermentation at 30°C. If thermophilic cultures are added, acidification capacities (pH values of 3.4 to 4.1 after 48 hours at 22°C) and cooking temperatures (42° to 48°C) are increased.

Thermophilic single-species cultures (*Lactobacillus delbrueckii* subsp. *bulgaricus*, subsp. *lactis*, or *Lactobacillus helveticus*) have acidification capacities that give pH 3.2 to 4.25 after 24 hours. pH values developed are between pH 4.10 after 15 hours at 37°C and pH 4.3 after 6 hours at 42°C. For these cultures, information on proteolytic activities is critical. Very often, polysaccharide (extracellular slime)–producing strains are added to increase viscosity.

Thermophilic *Streptococcus thermophilus* cultures for mild acidification, in contrast, have acidification capacities producing pH 4.3 to 4.65 after 24 hours at 42°C, pH 4.7 to pH 5.3 is obtained after 7 to 9 hours. Polysaccharide-producing strains are of prime importance for yogurt production to aid mechanical stability of the curd without addition of external stabilizers. Fast *S. thermophilus* cultures reach pH 4.4 to 4.6 within 6 hours of fermentation.

Cultures of multiple, thermophilic species contain a mixture of *S. thermophilus* and *Lactobacillus delbrueckii* subsp. *bulgaricus* for fast and strong acid production. pH 4.5 is obtained within 3 hours, the overall acidification capacities are around pH 3.40 to 3.65 after 24 hours at 42°C. After 2 hours at 42°C, pH values of 4.95 to 5.05 are obtained.

Thermophilic cultures for mild acidification (4.5 to 7 hours to obtain pH 4.5) contain *S. thermophilus* and *Lactobacillus acidophilus*. 24-hours fermentation capacities at 42°C are around 4.0 to 4.05. Additional species used in such cultures are *Lactobacillus delbrueckii* subsp. *bulgaricus* and *lactis* (slow, protease-weak strain) and several bifidobacteria. *Penicillium roqueforti* is available as semifast and fast cultures with piquant aroma potential, differing proteolytic and lipolytic capacities, and in color shades white, light blue-green, light gray-green, blue green, gray-green, and intensive dark blue-green. Ripening times with these cultures vary between 5 and 7 weeks. In addition, water exudation from the product and production of bitter taste are variable properties.

Penicillium candidum is available as fast or semifast culture with different macroscopic properties of the cheese surface mycelium: very white, medium high, normal density to cream colored, high mycelium, and very high density mycelium.

By definition, *Penicillium camemberti* has a blue-gray color. The available yeast cultures include *Debaryomyces hansenii, Candida utilis, Saccharomyces cerevisiae,* and *Mycoderma* species. Brevibacteria may be orange, yellow-orange, or cream colored cultures.

Propionibacterium freudenreichii cultures are available with different gas formation capacities. They have to be able to survive the cooking temperatures in Emmental manufacture (up to 55°C).

Pictures of some starter bacteria are shown in Figure 23-2 as they might be seen in a normal microbiological laboratory. They demonstrate that the rather unspectacular morphology is not an obvious criterium to identify these bacteria needing the mentioned physiological and molecular properties in addition.

A production scheme for modern bacterial starter cultures is outlined in Figure 23-4.

23.3.6 Quality Standards for Dairy Starter Cultures

(See also microbiological specifications in the catalogs of starter culture producers.)

It is usual to provide information on the performance of starter cultures under practical manufacturing conditions. Some of the important properties have been outlined in the previous section. In practice, a detailed technical information sheet is available for each culture, including information on bacteriophage types. The offered starter cultures must not contain pathogenic or undesirable spoilage microorganisms.

An example for freeze-dried or deep-frozen concentrated cultures suitable for direct inoculation of fermentation vats is given in Table 23-5. The high-risk pathogens *Listeria monocytogenes* and *Salmonella* species (Section 23.5) must be absent in 25 g; coagulase-positive staphylococci must not be detected in 10 g; coliforms should not be present in 1 g; and spoilage microorganisms like yeasts, molds, and enterococci, or undesirable gas-forming organisms, should be restricted to low numbers, which will not grow up to critical levels during fermentation. Freeze-dried or frozen cultures for the inoculation of bulk starter tanks may have stricter limits regarding yeasts, molds, enterococci, staphylococci, and also limits for sulfite-reducing anaerobes (clostridia; not detectable in 1 g) and mesophilic aerobic counts (less than 100 for frozen, and less than 1,000 for freeze-dried starter cultures g^{-1}).

23.3.7 Natural (Artisanal) Starter Cultures[81]

Some natural whey cultures have survived from traditional local cheese making into the age of modern microbiology, enabling an analysis of their composition. Table 23-6 gives examples from Italy and Switzerland. The natural culture listed in Table 23-6 is characterized by lactic acid bacteria (*S. thermophilus*, enterococci), which survive a 15 minute heating of raw milk to 65°C with subsequent incubation at 45°C. The other cultures described are characterized by the presence of heterofermentative lactobacilli (*Lactobacillus fermentum*) in addition to the main three thermophilic lactobacilli (*L. helveticus, L. delbrueckii* subsp. *bulgaricus* and

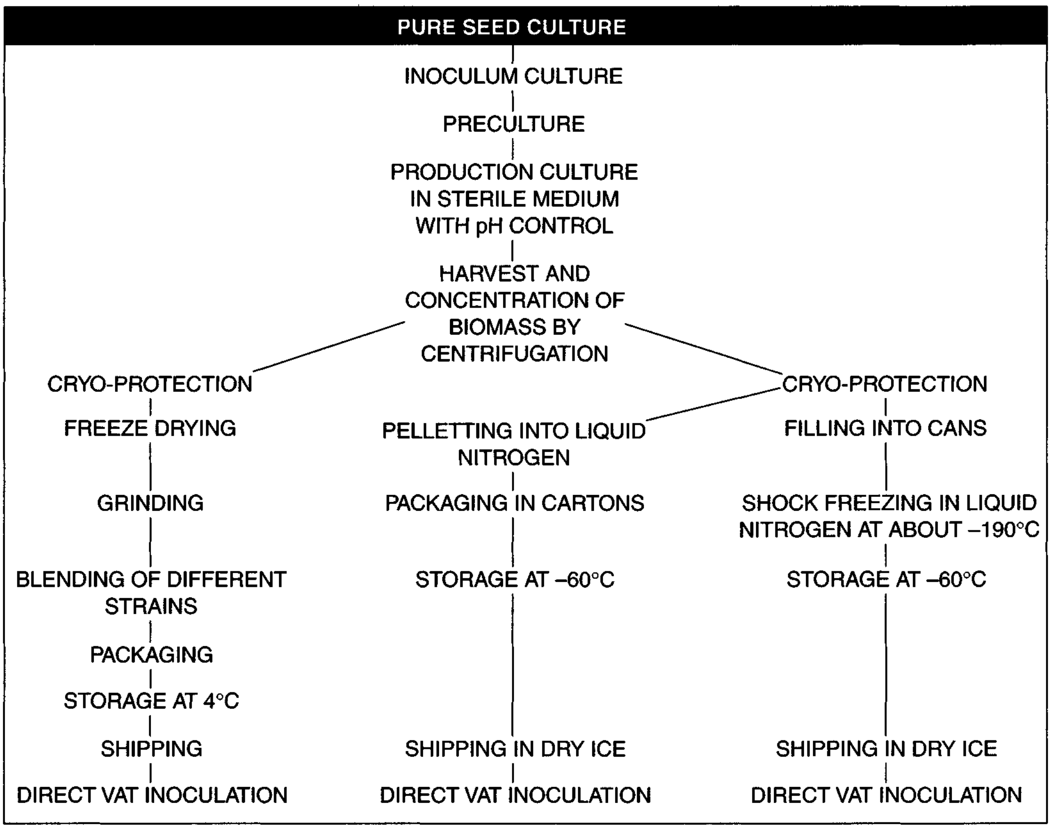

Figure 23-4 Schematic Outline for the Industrial Production of Modern Freeze-Dried, Deep-Frozen, Concentrated Starter Culture Preparations (for more details and references, see Teuber, 1993,[132] and Cogan and Accolas, 1996[18]).

lactis). Table 23-7 gives a detailed microbiological analysis of a natural whey culture used for the fermentation of buffalo milk to mozzarella in southern Italy.[19] This culture is an extremely diversified mixture of thermophilic and mesophilic lactic acid bacteria (streptococci, lactococci, and lactobacilli). A characteristic of this culture is the significant presence of at least 5% of the viable counts as enterococci (*E. faecalis* and *E. faecium*). Without reasonable doubt, enterococci in such cultures (and in raw milk yogurt and cheeses) originate from fecal contamination during milking, in contrast to differing recent explanations, which are not based on experimental data.

23.4 FERMENTED MILK PRODUCTS[16,34,136]

23.4.1 Outline of the Microbiological, Biochemical, and Hygienic Complexity

Before the invention of milk drying, pasteurization, UHT treatment, and sterilization, fermentations of milk were the only ways to conserve the nutritionally important milk ingredients, protein and fat. From the data given in Exhibit 23-1, it is clear that, at present, fermentation processes are probably used for only about one-third of the world production of cow's milk. The cheese production of about 15 million tons requires about 150 million tons of milk. The proportion used for cheese production may be higher in the case of goats' and sheep's milk. The fermentation of milk (eg, cow's, goat's) with defined starter cultures is still a very complex process because of the following conditions:

1. The substrate milk contains truly dissolved compounds like lactose, globular whey proteins, amino acids, vitamins, some minerals, as well as the casein micelles (50 to 300 nm in size) in addition to fat globules surrounded by a membrane composed of phospholipids and proteins.
2. During unstirred fermentation and production of lactic acid, the system changes from a liquid into a semisolid (coagulated milk) or solid (cheese) state. As a consequence, the microorganisms that are initially mobile become immobilized during fermentation.

3. During the fermentation of milk and ripening of cheeses, there are constant changes of the environmental conditions for the microorganisms involved. These include changes in pH, oxygen pressure, and water activity; available nutrients may decrease, and metabolic waste and byproducts (eg, lactic acid, propionic acid, acetic acid, certain amino acids, free fatty acids, biogenic amines, methylketones, diacetyl, formic acid, and benzoic acid) may increase. Within the mesophilic and thermophilic lactic acid bacteria, single strain, multiple strain/species, and undefined strain/species cultures are available enabling changes to be made to avoid susceptibility to bacteriophages. In technological terms, the activities of the culture regarding speed and amount of lactic acid formation, citrate transformation into diacetyl, and CO_2 evolution (necessary for cheese hole development) are part of the culture description.
4. If the final product is pasteurized (as is done for fresh cheeses), a clear definiton of the fermentation endpoint is possible. Cheeses and sour milks not heated after fermentation undergo continuing microbiological and biochemical changes. This should be kept in mind when data on composition are given in this chapter.
5. The times (days to months) and temperatures (6° to 54°) used in production of these foods may vary substantially. These two parameters are the main tools available for controlling the activities of microorganisms fixed inside the solid protein/fat/water matrix of cheeses.
6. The fermentation may be further complicated if a surface microflora develops during cheese ripening in addition to the internal microflora. Under these circumstances, the relative humidity of the atmosphere is of prime importance.

As stated in the introduction, all these tremendously complex fermentation processes have evolved by empirical application. Modern dairy biotechnology tries to imitate the traditional processes and products on a rational and microbiologically well-defined basis.

Two methods of coagulation of milk are used in dairy fermentations: (1) coagulation due to lowering of the pH value as a result of microbial metabolism (sour milk route), and (2) coagulation due to added proteases (chymosin/rennet route). The main fermented dairy products will be described according to this differentiation.

The curdling of milk necessary for the manufacture of sour milk products and cheese is the consequence of a destabilization of the colloidally dissolved casein micelles, which can be achieved biophysically by lowering the pH or biochemically-biophysically by means of the proteolytic enzyme preparation rennet or by a combination of the two processes. Milk protein consists of about 75% to 80% caseins and 15% to 25% whey proteins including lactoglobulin, lactalbumin, serum, and immune globulins. The casein fraction is heat resistant and acid labile, and the whey proteins are denatured by heating but remain in a solution in the critical pH range in dairy products around pH 4.

The caseins are organized into casein micelles between 50 and 300 mm in size and are made up of submicelles. There are about 70×10^{13} casein particles per ml of milk. The micelles of cow's milk contain 42% of α-casein (MW 23,615), 28% of β-casein (MW 23,983), and 14% of κ-casein (MW 19,023), together with 10% of other casein components, 2.9% of calcium, 0.5% of magnesium, 0.8% of organically bound phosphorus, 1.4% of nonbound phosphorus, 0.5% of citric acid, 0.3 of N-acetylneuraminic acid, 0.2% of galactose, and 0.2% of galactosamine. The isoelectric point of the casein micelle is at pH 4.6. The micelle is stabilized by hydrophobic interactions and salt bridges. Based on 1 mole of casein, the micelle contains 24 moles of calcium, 8 moles of organically bound phosphoric acid, 1 mole of inorganic phosphate, and 1 mole of citric acid, and can be regarded as a caseinate-calcium-phosphate-citrate complex. An experimentally substantiated, descriptive model of the casein micelle has been developed by Schmidt.[121]

Table 23-6 Characteristics of Some Natural Starter Cultures Used in Cheese Manufacture in Italy and Switzerland

			Microflora						
Cultures and Relevant Cheese	*Local Name*	*Preparation of Culture*	*Streptococcus thermophilus*	*Lactobacillus helveticus*	*Lactobacillus lactis*	*Lactobacillus bulgaricus*	*Lactobacillus fermentum*	*Lactococci*	*Enterococci*
Natural milk cultures									
Crescenza Italico Mozzarella Others	*Latto-innesto* *Latto-fermento*	Thermization (63°–65°C, 15 min) of raw milk; cooling to 45°C and incubation until a final acidity of 0.4–0.5% lactic acid is obtained (4.5–6 hr)	++						++
Whey cultures									
Water buffalo Mozzarella	*Siero-innesto* *Cizza*	Incubation of whey at the end of cheese making at room temperatures (cooling from 37° to 20°–22°C) until a final acidity of 0.9–1.1% lactic acid is obtained (16–18 hr)	++	++	++	+	+	++	++
Provolone	*Siero-innesto*	Incubation of whey at the end of cheese making at 30°–45°C; final acidity 1.0–1.3% lactic acid	+	++		++	+		
Pecorino Romano	*Scotta-fermento*	Heat treatment of whey at 80°–90°C for 20–30 min to deproteinize; incubation for 24 hr; inoculation of ricotta whey; incubation at 45°C for 24 hr; final acidity 0.7–0.8% lactic acid	+		++	++			
Grana	*Siero-innesto* *Siero-fermento*	Incubation of whey at the end of cheese making at 47°–52°C; final acidity 1.2–1.3% lactic acid	+	++	+	+	+		
Whey culture + rennet									
Emmental Gruyère Sbrinz	Fettsirtenmagen-Lab Présure à la "recruite"	Maceration of dried calf stomachs in whey at 39°–45°C, with or without deproteinization (by boiling at pH 5.0); final acidity 0.9–1.3 lactic acid	++	++	++	+	+		+

Note: Latto-innesto, latto-fermento = milk starter; *siero-innesto, siero-fermento, cizza* = whey starter; *scotta-fermento* = deproteinized whey starter; Fettsirtenmagenlab, Présure à la "recruite" = deproteinized whey starter with rennet.

Curdling of Milk by Lactic Acid Fermentation

With decreasing pH, the casein micelles lose calcium and phosphoric acid is dissociated. From a pH of 5.2 to 5.3, ie, even before the isoelectric point of 4.6 is reached, the calcium- and phosphorus-deprived micelles begin to precipitate. In this pH region, the coagulum formed occupies the entire original volume of the milk. Only by mechanical agitation (cutting and stirring) and raising the temperature (heating and cooking) does a further aggregation of the casein (syneresis) take place with a consequent excretion of whey from the coagulum.

Curdling of the Milk with Rennet

Rennet is an aqueous extract from the fourth stomach of unweaned calves, which is marketed in aqueous form or as rennet powder, or it may be replaced by chymosin produced by microbial fermentation.[130] The important constituent of rennet is the proteolytic enzyme chymosin (rennin, E.C. 3.4.4.3). Chymosin cleaves the κ-casein molecules very specifically between phenylalanine-105 and methionine-106. In milk, rennet-induced curdling is a two-phase process, which takes place only when sufficient calcium is available. In the absence of calcium, κ-casein is cleaved, but there is no coagulation. In a third phase, during the ripening of the cheese over long periods, other caseins are also hydrolyzed slowly. Pepsin and chymotrypsin act similarly. If cheese is made from raw milk, the milk-derived proteolytic enzyme plasmin contributes considerably to proteolysis during cheese ripening (Table 23-8).

23.4.2 Sour Milk Products[136]

General Aspects

Under suitable conditions (22° to 45°C), the lactic acid bacteria from the very complex microflora present in raw milk[30] are selectively enriched, can multiply at a high rate, and thereby ferment part of the lactose present in the milk to lactic acid. The resulting decrease of the pH and the redox potential suppress many of the other species of microorganisms of the original milk flora and, in particular, the causative agents of spoilage and disease, such as staphylococci, enterobacteria, and clostridia without, however, killing them. This lactic acid fermentation produces from milk a keepable, pleasant-tasting, and highly nutritious product.

In various regions of the world different practices for milk treatment have developed on the basis of the existing climatic conditions. Depending on the type of milk used, products arise such as curdled (sour) milk in Europe, yogurt in the Balkans, kefir in the

Exhibit 23-1 Main Global Dairy Products in 1995 Obtained from 295 Million Dairy Cows

Overall milk production	528,616,000 tons

Caucasus, koumiss in Central Asia, dahi in India, and leben in Egypt and Palestine. The acidification in the sour milk product (pH 4.0 to 4.5) brings about a precipitation of the casein in the form of fine flocs.

The definition of sour milk products is that they are obtained by the use of lactic acid bacteria (lactococci and lactobacilli) without removal of whey after the end of fermentation. Special products may contain additional microorganisms like yeasts and certain probiotic bacteria. The initial substrate is pasteurized or thermized, homogenized milk such as whole milk, partially defatted milk, skim milk, milk the fat content of which has been adjusted by the addition of cream, and cream. The amount of dry matter in the milk can be raised by evaporation or by the addition of dry skim milk powder or, in the case of yogurt, with edible casein. The sour milk products include (1) milk soured with mesophilic cultures of lactic acid bacteria, eg, sour milk, curdled milk, sour cream, buttermilk, (2) milk soured with thermophilic lactic acid bacteria, eg, yogurt, and (3) milk processed with special mesophilic or thermophilic cultures, which contain, in addition to typical lactic acid bacteria, other bacteria or yeasts, eg, acidophilus milk, kefir, or koumiss.

For the preparation of curdled milk,[69,112,113] the fat-adjusted and pasteurized milk is cooled to 22° or 30°C, depending on the process, and is inoculated with 2% to 5% or 0.1% to 1% of cultures, respectively. The main cultures that are used consist of *Lactococcus lactis* subsp. *cremoris, Lactococcus lactis* subsp. *lactis* biovar *diacetylactis*, and/or *Leuconostoc cremoris*. Souring (to about pH 4.6) and coagulation take place in the souring tank in about 16 hours. The sour milk is then cooled to 7° to 10°C and packed (Table 23-9). In another process, the milk is packed immediately after the addition of the culture, and it is soured and curdled in the package. Souring at low temperatures promotes the development of aroma.

Sour Cream

To prepare this, pasteurized cream is adjusted to a fat content of 10% or 20% to 25%, homogenized, and incubated at 18° to 20°C with 2% to 4% of a creamery culture. After about 9 hours, a pH of between 5.1 and 4.9 has been reached. After this, the product is cooled to 4°C, packed, and stored cold. Post-fermentation pasteurization is applied frequently.

Yogurt[108,113]

The sour milk product yogurt originated from the Balkans and the Middle East. Goats', ewes', and cows' milk are used for its manufacture. Solid yogurt is a product of milk-white color with a porcelain-like smooth surface. It possesses a creamy solid gel-like consistency, can be cut, and does not release whey. It has a fresh lactic acid smell and its taste is characteristic, pleasant, full, and slightly to intensely sour. Yogurt is manufactured from heat-treated milk of various fat grades or from cream, and also from milk the dry matter of which has been increased by evaporation or addition of milk powder or casein, using cultures of lactic acid bacteria that are specific for this purpose. As a product ready for consumption, it usually contains large numbers of living lactic acid bacteria ($>10^6$ to 10^9 ml^{-1}).

The specific culture used for the manufacture of yogurt consists of thermophilic lactic acid bacteria from the species *Streptococcus thermophilus* and *Lactobacillus delbrueckii* subsp. *bulgaricus*, which live together in symbiosis. In place of *L. bulgaricus*, it is possible occasionally to use *L. helveticus*. The yogurt organisms are found in milk curdled in hot countries but can otherwise be isolated from calf stomachs. The two species of bacteria activate one another. *S. thermophilus* rapidly lowers the redox potential and produces some formic acid, which promotes the growth of *L. bulgaricus*, and some carbon dioxide. *L. bulgaricus* is more strongly proteolytic. It produces some of the amino acids and peptides required by *S. thermophilus*. Thus, the two species of bacteria grow in a mixed culture more rapidly and produce more aroma components than either of the strains alone. In a traditional yogurt culture, the two species are present in a numerical ratio of about 1:1. This composition can be adjusted by the choice of incubation temperature. Since *S. thermophilus* has its temperature optimum at 40° to 45°C and *L. bulgaricus* at 45° to 50°C, cultivation temperatures above 45°C leads to the faster multiplication of *L. bulgaricus*.

In the manufacture of yogurt, *S. thermophilus* multiplies faster at the beginning of fermentation and starts the souring process (this explains the name starter culture!). At an acid concentration of about 0.6%, its activity declines, to die out at about 0.8% of lactic acid. *L. bulgaricus* then takes over the souring process to produce a maximum concentration of 1.5% to 2% lactic acid. A mild yogurt ready for consumption contains 0.8% to 0.9% lactic acid, and a sour yogurt 1.0% to 1.3%. The fermentation products are mainly lactic acid [D(–) and L(+)] and small amounts of volatile fatty acids, carbonyl compounds, and alcohols. The characteristic taste of yogurt is evoked by a bouquet of aroma compounds, the synthesis of which starts at a pH of 5, falls off in the pH range of 4.4 to 4.3, and diminishes greatly at about pH 4. Prolonged storage at low values leads to loss of the most important aroma components. The characteristic component of the yogurt aroma is acetaldehyde, others are acetone, ethanol, butan-2-one, diacetyl, and ethyl acetate. The total acid in yogurt is made up of 59% lactic acid, 28% citric acid, 5.3% acetic acid, 2.4% formic acid, 2.3% succinic acid, and small amounts of other acids.

Manufacture of Yogurt (Table 23-9). Because of the extreme susceptibility of the yogurt microflora to inhibitors and antibiotics, the milk must be completely free of such contamination. It is adjusted to the desired fat content and necessary dry matter content. After this it is heated to 60°C and, to improve the taste and also to increase the firmness of the gel, it is homogenized at a pressure of about 200 bar and is finally heat treated in the pasteurizer at 75° to 95°C for between 5 and 40 minutes. After cooling to the ripening temperature of 42° to 45°C, 1.5% to 3% of yogurt starter culture is added to the milk. The subsequent steps differ depending on whether solid yogurt or stirred yogurt is being produced.

Solid Yogurt (Table 23-9). A rapid decrease of the pH and the incipient coagulation of the milk leads to a steep rise in viscosity. Because a uniformly solid structure not releasing whey is required, after inoculation the milk must be filled into containers within 20 minutes. Incubation is carried out at 42° to 45°C for 2.5 to 3 hours. When a pH of 4.6 has been reached, the product must be cooled as rapidly as possible to temperatures below about 5°C. This substantially reduces the metabolic activities of the yogurt flora in order to avoid oversouring. Slight post-souring takes place even at these temperatures. From the sealing of the yogurt containers until cooling, shaking must be avoided at all costs in order to prevent the appearance of fissures in the gel that is forming, with an associated release of whey. Before filling of the starter culture–containing yogurt-milk into containers, flavoring components (preferentially pasteurized) of diverse types in the form of fruit, honey, jam, and others, can be added to the containers to produce a range of products.

Stirred Yogurt. In the manufacture of stirred yogurt, incubation is carried out in the ripening tank. Shortly before a pH of 4.7 has been reached, the tank is cooled so that the yogurt can be stirred at pH values of 4.7 to 4.6 at about 20°C. The substrate is then cooled in a heat exchanger to 5°C and is either filled directly or is first mixed with flavoring components and then filled into the selling containers. Because of the tendency to post-souring, storage must take place at 5°C or lower.

Kefir

This originated from the Caucasus and was obtained from cows', goats', or ewes' milk. Today, kefir is produced in large amounts, particularly in Russia, where in 1971 about 1,116,000 liters of whole-milk kefir was produced. In many countries, the popularity of kefir is only slightly less than that of yogurt. Kefir is a thick-flowing, creamy, slightly effervescent or foaming beverage of milk-white color. It contains 0.8% to 1% of lactic acid, 0.3% to 0.8% of ethanol, and carbon dioxide. The alcohol and carbon dioxide, together with small amounts of diacetyl, acetaldehyde, and acetone, contribute greatly to its characteristic refreshing taste. Today, kefir is manufactured from pasteurized milk or cream, the fat content or dry matter content of which has been adjusted by the use of cultures specific for this purpose.

The kefir cultures or kefir grains (Figure 23-5) are whitish-yellow clumps of pea to walnut size with cauliflower-like shape. These agglomerates, the structure of which consists of the sparingly water-soluble but highly swellable polysaccharide kefiran and acid-coagulated casein, contain a symbiotic microflora. In addition to lactose-fermenting yeasts[37] such as *Saccharomyces kefir* and *Candida kefir* (5% to 10% of the culture), it contains homofermentative and heterofermentative lactobacilli (eg, *Lactobacillus kefir*), mesophilic lactococci, flavor-forming *Leuconostoc,* and acetic acid bacteria (mainly *Acetobacter pasteurianus*). The composition of the mixed kefir culture is variable according to the process, the climate, or the milk used without, however, this giving rise to fundamental changes.

Manufacture of Kefir (Table 23-9). The prepared milk is heated in the heat exchanger to 70°C and is then homogenized and heat treated in the pasteurizer at 85°C for 30 minutes. Pasteurized milk is cooled to the fermentation temperature of 18° to 28°C, usually 22°C. In the ripening vessel 3% to 5% of kefir culture is added to the milk and, depending on the amount of inoculum, it is incubated for 10 to 20 hours. When a pH of 4.6 to 4.4 has been reached, the soft coagulum is stirred. The kefir grains are then separated off. These may, after being washed well with cold germ-free water, be added to a new production batch. The kefir is cooled to 7° to 12°C and is then filled either into glass bottles or plastic beakers and sealed. It can be sold directly for consumption or it can be left to post-ripen at 7°C for 24 to 48 hours, depending on the taste. When an airtight seal is opened, kefir tends to foam. If kefir is stored in bottles the closure of which permits carbon dioxide to escape, alcohol is also lost from the product. Kefir filled into plastic containers tends to cause the containers to swell and blow. This is a normal behavior for a living fermented product and does not mean that the product is spoiled.

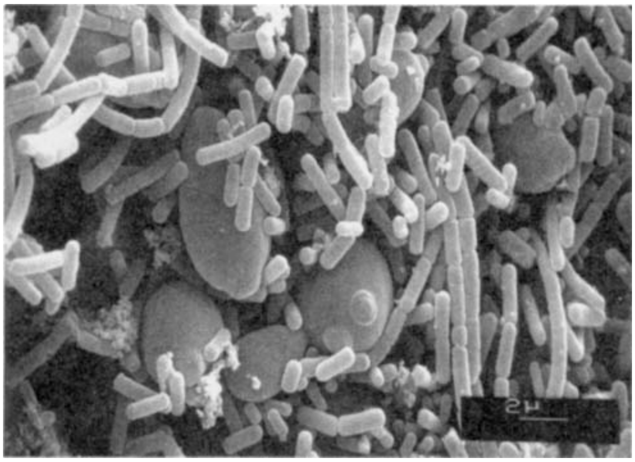

Figure 23-5 Scanning Electron Micrograph of the Surface of a Kefir Grain Showing Budding Yeast Cells, and Long and Short Rod-Shaped Lactic and Acetic Acid Bacteria. *Source:* Reprinted with permission from H. Neve, Analysis of Kefir Grain Starter Cultures by Scanning Electron Microscopy, *Milchwiss,* Vol. 47, pp. 275–278, © 1992, Volkswirtschaftlicher Verlag.

Koumiss

Koumiss, a homogeneous, slightly foaming, sour milk drink, comes from Central Asia. It was originally prepared from mares' milk (composition in Table 23-2). The product is recommended today, particularly in Russia, for dietetic treatment in the case of intestinal diseases because of its wholesomeness, ready digestibility, and vitamin content. Its taste is due to a simultaneous lactic acid and alcohol fermentation, and the taste-affecting metabolic products of the organisms of the koumiss culture. Koumiss contains 0.7% to 1.8% lactic acid, 0.5% to 2.5% ethanol, and carbon dioxide. In 1980 in Bashkir, 200,000 mares were available for the production of milk. In addition to this, modified cows' milk is being used in increasing amounts. Cows' and mares' milks have substantially different chemical compositions. In particular, the lower protein content in mares' milk and the ratio of casein to whey proteins of approximately 1:1 results in only partial coagulation of the milk, which is characteristic for koumiss. Consequently, the composition of skimmed cows' milk intended for the manufacture of koumiss is brought close to that of mares' milk by the addition of whey proteins and it is then fermented.

The cultures used are mixed cultures of yeasts (*Torula, Kluyveromyces, Candida,* and *Brettanomyces*), lactobacilli (*Lactobacillus delbrueckii* subsp. *bulgaricus, L. acidophilus*), and lactococci and streptococci *(Lactococcus lactis, S. thermophilus).* Yeasts and mixtures of bacteria are preincubated separately and are then added to the milk in ratios of 1:1–1:10. In principle, the manufacture is similar to that of kefir.

Presently, in many countries of the world, sour milk products containing typical inhabitants of the human gut (*Lactobacillus acidophilus, L. johnsonii, L. casei* subsp. *rhamnosus, Enterococcus faecium, Bifidobacterium bifidum,* and other bifidobacteria) are on sale (Section 23.6). Because these bacteria have physiological properties differing from those of traditional starter cultures, production of such fermented products needs specific fermentation conditions as exemplified for *Lactobacillus acidophilus.*

This bacterium has its temperature optimum at 35° to 38°C, the organisms of the cream-souring culture have theirs at 25° to 27°C, and those of yogurt at 40° to 48°C. It is therefore understandable that when *L. acidophilus* (or the closely related *L. johnsonii*) is added to normal starters and these mixed cultures are used under the conditions normal for the production of sour milk or yogurt, the resulting products only contain low numbers of *L. acidophilus.* Consequently, other ways have been found for the manufacture of *L. acidophilus*-containing milk products, eg, by fermentations at reduced temperatures (35° to 40°C). Alternatively, the different starter bacteria are fermented separately under optimum conditions. The final products are blended after fermentation.

Storage Life of Sour Milk Products[107]

The increasing popularity of sour milk products, the concentration and expansion of production units, and specialization of the factories for production of single types of product are leading to an increasing supply and more widespread and distant markets. This leads to a demand for an improvement in the shelf life of these products. The elimination of contaminants (eg, coliforms, yeasts, and molds) must be achieved by recontamination-free fermentation of the pasteurized substrate milk coupled with aseptic filling. Post-souring can be prevented only by post-fermentation pasteurization or sterilization of the fermented products. Although such sour milk products are on the market, sterilization of products, resulting in a very long shelf life, may not be desirable because these are essentially regarded as "fresh" foods, and would lose their desirable or organoleptic properties during long storage even under sterile conditions. In some countries, a "pasteurized or sterilized yogurt" must not carry the name yogurt, which is reserved for products containing living lactic acid bacteria. Post-fermentation pasteurized "yogurt" may in such countries be labeled as "sour milk product."

23.4.3 Cheese[27,46,101,136]

Cheeses are fresh products or products in various stages of ripening that have been manufactured from curdled milk. In contrast to sour milk products, the curdling of the milk is achieved either by acidification or by means of proteolytic enzymes such as calf rennet, pepsin, or microbial rennet. A further difference is that in cheese part of the aqueous phase of the milk is eliminated as whey during processing. The larger the amount of whey removed, the harder is the consistency of the cheese and the higher is its dry matter content. The degree of elimination of whey is determined essentially by the syneresis (separation of hydrophobic colloids) of the coagulum or curd (coagulated casein). The degree of syneresis, and therefore the release of whey during cheese manufacture, is increased by mechnical stirring and, in particular, by heating of the coagulum. The manufacturing process for a cheese can be subdivided into the following steps:

1. **Preripening of the cheese milk.** Raw milk or pasteurized milk is inoculated with a small amount (0.1%) of a culture of lactic acid bacteria and is incubated overnight at 12°C. This preripening step acts essentially as a process of conditioning the milk for the manufacture of cheese. The exact biochemical processes that occur are not yet known. Undoubtedly, an important factor is the resulting decreased redox potential of the milk. In the production of raw milk cheese, this step may lead to the multiplication of undesirable and pathogenic bacteria if present.[29]
2. **Renneting of the milk and curdling.** The preripened milk inoculated with starter culture is coagulated either by lactic fermentation alone (see *Fresh Cheeses* below) or by the addition of a rennet preparation.
3. **Cutting of the coagulum.** This process is necessary in order to induce the release of the whey and to allow formation of cheese loafs.
4. **Heating/cooking (scalding) of the cheese curd.** Heating has the aim of promoting syneresis (see above) and, consequently, the release of whey. The larger the amount of whey to be removed, the longer and the hotter the heating process. Temperatures above 45° to 50°C reduce the survival of enteric bacteria and yeasts. Thus, lowering of the so-called cooking (scalding) temperatures could possibly produce microbiological risks if raw milk is used for cheese making.
5. **Elimination of the whey and formation of the cheese mass.** In the case of soft and hard

cheeses, the whey is removed by mechanical means (eg, sieves or cheesecloth), in the case of fresh cheeses curd separators (centrifuges) are used for this purpose.

6. **Pressing the cheese into forms.** This process has the aim of eliminating more whey, after the final shaping of the cheese. During pressing, lactic acid fermentation proceeds further.
7. **Salting the cheese.** If the curd has not been dry salted before the formation of the cheese blocks, the shaped and molded cheeses are immersed for some time (a few hours to days) in a salt bath (brine is normally a concentrated or saturated solution of sodium chloride in water). Certain types of cheese can be dry salted (eg, Roquefort, cheddar).
8. **Ripening of the cheese.** Ripening aims to condition the final cheese product to produce the desired consistency, taste, and aroma. The microbiology and biochemistry of cheese ripening is not yet known in all its details. Important aspects are listed in Tables 23-9, 23-10, and Exhibit 23-2.[31]

Mair-Waldburg[88] lists hundreds of varieties of cheese. Below, the manufacture of some characteristic varieties of cheese are described in more detail.[45,88,111]

Fresh Cheeses

Fresh cheeses are natural, unripened products. They are manufactured from pasteurized milk of adjusted fat content by the use of starter cultures and rennet or rennet substitutes or with cultures alone by the precipitation of the casein and the separation of whey, and are marketed in the fresh state. Shelf life can be improved by heat treatment (pasteurization) after fermentation. Fresh cheese may be modified by incorporating flavoring additives in the cheese mass. The fresh cheeses include quark and granular fresh cheese (cottage cheese).

Quark (Table 23-9). This forms the main fresh cheese product in a large part of Europe. It is manufactured only from pasteurized skim milk, the fat content of which has been adjusted or, for the higher-fat grades, from milk with added cream. Quark is prepared with souring cultures and small amounts of rennet (sour rennet quark) or starter cultures alone (sour milk quark). In the low-temperature process at 20° to 30°C (time of souring 15 to 22 hours), mesophilic cultures, creamery cultures, or single-strain cultures of *Lactococcus lactis* subsp. *cremoris* are used. In the warm process at 38° to 40°C (souring time 3 to 5 hours), thermophilic lactic acid bacteria (*S. thermophilus* and *Lactobacillus delbrueckii* subsp. *bulgaricus*) are used.

The manufacture of quark involves the following steps:

1. **Preparation of milk.** Milk of adjusted fat content from the primary stock tank is heated to approximately the temperature of pasteurization, homogenized, and then pasteurized at 72°C for 15 seconds or at 85° to 95°C for a few seconds, cooled to 20° to 27°C or 38° to 42°C, according to the process being used, and pumped into ripening tanks with a capacity of 15,000 to 50,000 liters.
2. **Souring and curdling.** In the souring tank, 0.5% to 2% of the starter culture in the low-temperature process and 3% to 4% in the warm process is added, with, if required, the rennet preparation, and the mixture is thoroughly stirred for

about 2 minutes. Then the milk is left to rest until it has curdled. Small amounts of rennet are said to accelerate the coagulation through slight proteolysis and therefore also to have a favorable effect on the stability of the consistency of the casein gel.

3. **Cutting and stirring.** After 8 to 12 hours in the low-temperature process, or 1 to 3 hours in the warm process, when a pH of 4.8 has been reached, the coagulum is cut by an integrated cutting and stirring device in the souring tank into sections with an edge length of about 10 to 20 cm and is slowly stirred. In another 6 to 8, or 1 to 2 hours, with souring proceeding further, whey slowly separates out and the coagulum settles in the whey.
4. **Separation.** As soon as the pH has declined to 4.65 to 4.6, the stirring is stopped and the supernatant whey is run off. After this, the quark and the residual whey are removed from the tank. The quark can now be heat treated at 60°C to stop the activity of the rennet and to kill recontaminants and starter bacteria, ie, to prolong shelf life. Then, at a temperature of 30°C, the substrate passes through the quark separator for the elimination of more whey and for the adjustment of the desired dry matter content of the product. After this the quark is cooled to 4° to 8°C.
5. **Mixing.** The quark is processed to a uniform consistency in a kneading and mixing machine. Pasteurized cream, spices, or fruit preparations may be incorporated at the same time. The finished product is first stored in a silo and is then fed into packaging devices where filling is carried out with the greatest possible efforts to avoid recontamination. Quark pumps, piping, separators, and mixing devices of the unit must be so designed that the acid-coagulated casein micelles are not damaged by shear forces, which would lead to a continuing release of whey.[69] At refrigeration temperature, shelf life is about 3 to 4 weeks. Pasteurized and aseptically packed quark may keep for the same length of time at room temperature. However, because milk always contains a few heat-resistant ascospores of *Byssochlamys nivea*,[39] outgrowth of these spores will spoil quark under these conditions within 5 to 6 weeks of storage.

Cottage Cheese. Cottage cheese is a fresh cheese specialty. In the United States (US), it forms the main fresh cheese product. Cottage cheese is prepared from pasteurized skim milk with the addition of starter cultures, and rennet, by the acid coagulation of casein, and by special further heat treatment producing a granular product. To improve its taste, it is mixed with cream and common salt, and filled into containers.

The manufacture of cottage cheese involves the following steps (Table 23-9):

1. **Preparation of the milk.** Skim milk is homogenized and pasteurized (72° to 75°C for 15 seconds).
2. **Fermentation.** The starter cultures used are a mixture of mesophilic bacteria, mainly *Lactococcus lactis* subsp. *cremoris*, a small proportion of *L. lactis* subsp. *lactis*, and from 1% to a maximum of 3% of aroma-forming agents (*L. lactis* subsp. *lactis* biovar *diacetylactis* and/or *Leuconostoc cremoris*). Larger proportions of aroma-forming agents in the culture would affect the product adversely by the pronounced formation of gas. To facilitate curdling and the release of whey and to improve the granular texture by proteolysis, small amounts of rennet may also be added to the milk. The amount of starter culture and the temperature determine the time until the milk curdles.

   Milk, starter culture, and any rennet are mixed directly in the cheese vat and the mixture is left unstirred until it curdles. However, the milk may also be preripened by the starter culture until a pH of 5.7 is reached. It is then pumped into the cheese vat with the addition of the desired amount of rennet. The vats contain between 5,000 and 12,000 liters of milk. They are provided with cutting and stirring devices and also with heatable jackets. In the pretreatment of milk, up to the stage of the coagulation of the casein, any introduction of gas bubbles, whether by entrainment during pumping or stirring or through gas-forming microorganisms, must be avoided because the production of curds containing bubbles of gas makes processing difficult and causes reduction of yield.
3. **Cutting and stirring.** The solid curd with a pH of 4.7, corresponding to 0.4% to 0.5% of lactic acid, is cut into pieces with an edge length of 1 to 2 cm. Slow stirring prevents the pieces of curd from coalescing again and promotes the release of whey. Pronounced turbulence in the vat, which leads to the abrasion of cheese dust from the pieces of curd, has to be avoided.
4. **Scalding.** About 30 minutes after cutting, the contents of the vat are heated quite slowly to

temperatures of 42° to 60°C by passing hot water or steam into the jacket of the vat with simultaneous stirring and are left under these conditions for some time. This promotes the uniform release of whey from the grains of curd, so that a firm elastic curd arises with no formation of skin. This process lasts 1 to 3 hours.

5. **Washing.** After this, part of the whey is run off and, with stirring, the grains are washed with cold germ-free water and finally with ice water, which cools it to 8°C, and the water is run off.
6. **Mixing.** The curd is mixed with cream and, if desired, with the addition of salt. Spices or fruit preparations may also be added. After this, the granular fresh cheese is filled into packages. Composition of cottage cheese is water, 78.5%; protein, 12.3%; fat, 4.3%; lactose, 3.3%; and lactic acid, 0.4%. Stabilizers (eg, gums and starch) and the preservative sorbic acid may be added. Granular fresh cheese, especially when it contains flavoring additives, should be stored at 5°C or lower in order to retain its organoleptic quality. Shelf life is several weeks.

Sour Milk Cheese, Harzer Cheese

Sour milk cheeses, in contrast to fresh cheeses, are made from lactic acid–coagulated milk (sour curd) with additional ripening stages. The production of these cheeses is limited and is illustrated with reference to Harzer cheese (Table 23-9). Harzer cheese was originally manufactured from sour milk quark, but today it is also made from quark that has been obtained by a mixed rennet–lactic acid coagulation process (see above). The lactic acid fermentation can be carried out with mesophilic cultures (*Lactococcus lactis* subsp. *lactis* and *cremoris*) or with thermophilic cultures (*Lactobacillus helveticus, S. thermophilus,* etc). The dry matter content should be at least 32%. Quark from various productions and manufacturers is milled to walnut size and mixed with 3% to 4% of salt (NaCl) and 0.5% to 1.5% of ripening salts ($NaHCO_3$, $CaCO_3$). This is intended to neutralize part of the lactic acid in order to give a pH of 4.8 to 4.9. A further decomposition of the acids by yeasts (see section on surface ripened cheeses) is achieved by storage at room temperature for between several hours and one day. After fine comminution, the curd is shaped in special machines. The freshly formed cheeses are incubated on boards at 20° to 25°C in 95% atmospheric humidity for 2 to 3 days. During this process, the surface of the cheese is deacidified by film-forming yeasts. After the formation of a light yellow smooth skin, the cheeses are coated on all sides with a solution of 50 to 75 g of salt (NaCl) and 50 to 100 ml of a culture of *Brevibacterium linens* in a liter of water. After drying overnight, the cheeses are transferred to the ripening room where, at 12° to 18°C and a relative humidity of 90% to 95%, the typical red streak is formed. The cheeses can then be packaged and marketed.

Rennet Cheeses

The main varieties of cheese are made from rennet-coagulated milk. They are distinguished on the basis of their dry matter content as hard, semi-hard, and soft cheeses (Tables 23-10 and 23-11). Because there are many detailed recent reviews,[45,111] the present discussion concentrates on the basic description of some typical and important traditional cheese varieties that dominate modern cheese production and that demonstrate the microbiological, biochemical, and technological principles of cheese production, namely Emmental (Swiss) cheese, cheddar cheese, Romadour as an example of a surface-ripened brick cheese, Roquefort as an example of a blue mold–ripened cheese, Camembert as surface-ripened white mold cheese, mozzarella as a product heated after fermentation (pasta filata), and feta as a pickled cheese. These production outlines are the basis for understanding the resulting microbiological and hygienic problems described at the end of this chapter.

Emmental (Swiss) Cheese.[127] This cheese type is often regarded as the "King of all cheeses" because it represents the biochemically most sophisticated and hygienically as well as organoleptically most accepted product made from raw milk. The underlying biochemical reactions (lactic acid fermentation, CO_2 production leading to hole formation, and propionic acid fermentation) are given in Figures 23-6, 23-7, and 23-8. For the steps in the manufacture of Emmental cheese see the outline in Table 23-10.

Emmental cheese is produced mainly in Switzerland, Germany, Finland, France, and Austria from raw milk, but increasingly from pasteurized milk on a worldwide basis. There is a classical procedure of manufacture in the cheese vat in which 1,000 liters of milk give one large loaf of cheese. Currently, however, many large-scale manufacturers process up to 12,000 liters of milk in each cheese vat. The evening milk preripened overnight (12°C, temperature reached by the evening milk when cooled overnight with tap water) is mixed with the fresh morning milk. The added starter culture consists of 1% to 2% of a culture of thermophilic streptococci (*S. thermophilus*) and lactobacilli (eg, *Lactobacillus*

helveticus or *L. delbrueckii* subsp. *lactis*) in whey. In addition, a few drops of a culture of propionic acid bacteria must be added. The curdling time with rennet is about 30 minutes. The cutting of the curd (to 1 cm) and preliminary curd formation require 45 minutes. The mixture of curd and whey is heated with stirring (called cooking) to 53° to 55°C within 30 to 40 minutes and is stirred for another 30 to 60 minutes. At some stage here as the curd reaches a temperature of about 38° to 40°C, the starter bacteria begin to multiply. After cooking, the grains of curd are about 2 to 3 mm in size. After the settling of the curd, it is taken up with a cloth and placed into molds. First, it is compressed under a load of 500 kg for 20 minutes, and then under 1,000 kg for 60 minutes, and finally under 1,200 kg. During this procedure, it must be turned several times. After overnight pressing, the lactose should have been fermented completely to lactic acid (Figures 23-6 and 23-7). The pH of the cheese is then about 5.25. After this, the cheeses are placed in a salt bath (saturated NaCl) for 2 to 3 days at 15°C. The cheeses removed from the brine are dried in the salting room, which requires about 10 to 14 days. The cheeses are transferred into the warm room for 6 to 8 weeks. At temperatures of 22° to 24°C, the lactic acid formed is fermented by the propionic acid bacteria to carbon dioxide, acetic, and propionic acid, which gives rise to the characteristic formation of "eyes" (Figure 23-8) and to the development of the characteristic taste of the Swiss cheese. After the conclusion of gas formation, the cheeses are ripened in the storage cellar at 10° to 13°C. During this time, the surface of the cheeses must be washed regularly to remove the fungal coating that forms. The optimum time of ripening is 6 months and the maximum time of storage is a further 12 months at 15°C.

Late-blowing of hard cheeses is caused by spore-forming bacteria, eg, *Clostridium tyrobutyricum*, which ferment the lactic acid not to propionic acid but to butyric acid and hydrogen.[143] These bacteria cannot be avoided in the milk when the cows are fed with fermented fodder (silage). For this reason, in the German and Swiss production the feeding of silage is forbidden if the milk is to be supplied for the preparation of Emmental cheese. If legal, *C. tyrobutyricum* spores may be eliminated by hydrogen peroxide/catalase, addition of lysozyme to milk[60] or bactofugation of the cheese milk.[77] The use of nitrate, as in the case of Gouda manufacture in Holland and Germany,[142] is not acceptable for Emmental cheeses because it is not permitted, and also because it inhibits the propionic fermentation. Another fermentation failure is the so-called "Nachgärung" (late fermentation) in which, after the "eyes" have been formed, the production of carbon dioxide does not stop. This leads to fissures in the cheese and therefore to a lowering of its commercial value, although not always to an effect on the taste of the cheese. The microbiological reasons for this occurrence are so far unknown, but it is probably caused by contaminating bacteria such as enterococci and certain proteolytically active lactobacilli from the raw milk.

Cheddar Cheese. Cheddar cheese is produced mainly in the United Kingdom (UK), the US,

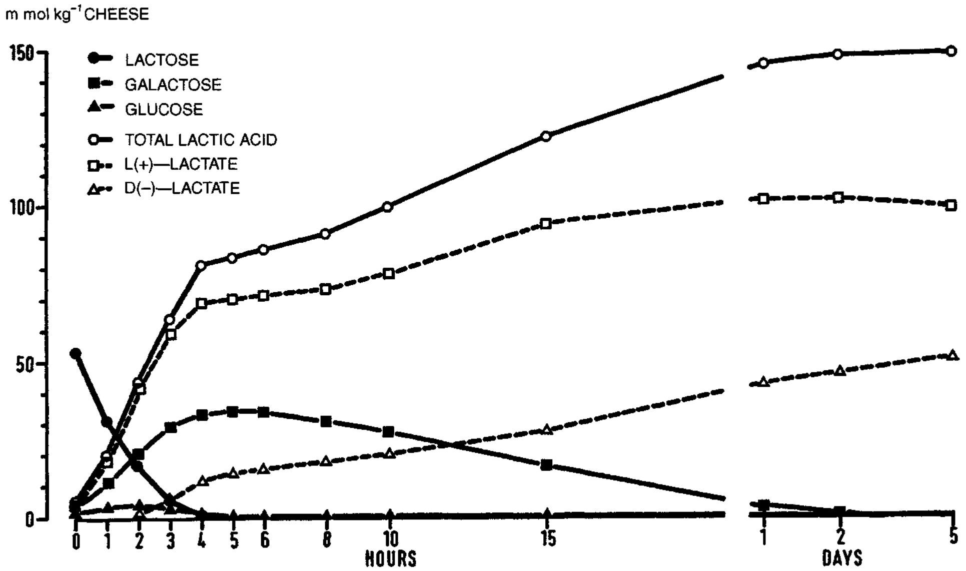

Figure 23-6 Carbohydrate Metabolism in a Young Emmental Cheese during the First Hours and Days of Manufacture. (See text and Table 23-10 for specific technological steps). *Streptococcus thermophilus* starts the fermentation by conversion of lactose into galactose and glucose, which is fermented to L(+) lactic acid within 4 hours. Galactose is excreted into the whey medium. *Lactobacillus delbrueckii* subsp. *lactis* (or *L. helveticus*) takes over the following fermentation converting galactose into D(−) lactic acid from 4 to 20 hours of fermentation, corresponding to the pressing stage. Courtesy of Swiss Federal Dairy Research Station, Liebefeld, Bern, Switzerland.

Canada, Australia, and New Zealand.[74] For steps in the manufacture see Table 23-10. The milk for its manufacture is pasteurized at 72.2°C for 15 seconds, cooled to 31°C, and is then treated with 1.5% of a single- or multiple-strain starter. Rennet (18 ml per 100 kg of milk) is stirred mechanically into the vat. The curdling time is from 30 to 35 minutes.

The curd is cut into cubes with a size about 1 cm^3. Five minutes after the end of this process, and within less than 30 minutes, the material is heated (scalded) to 38° to 39°C. The mixture is stirred at this temperature until the acidity in the whey reaches 0.15% of lactic acid (about 2.5 hours). The curd is allowed to settle and the whey is run off through filters. A rake-type stirrer is then drawn through the mass of curd several times during a period of 20 minutes in order to achieve the desired grain size. During this process, the acidity rises to about 0.23% to 0.24% of lactic acid. The mass of curd is now heaped up in order to achieve coalescence (cheddaring). After this procedure, pieces weighing 8 to 12 kg are cut out from this mass of curd and placed in layers above one another. During a period of storage of about 2 to 2.5 hours, the lactic acid content rises to 0.5% to 0.6% with a simultaneous drainage of whey. The cheddared blocks are then milled to form shreds of curd and are salted (about 3 kg of salt 100 kg^{-1} of cheese mass). Salted curd is transferred into cheese molds and pressed. After this, the cheeses are taken from the molds and coated with plastic foil or hot wax. In this form they are placed in the ripening cellar. They remain there at 7° or 10°C under a relative humidity of 55% for 1 to 12 months.

Romadour Cheese.[110] The pasteurized milk is treated with 0.2% to 0.5% of mesophilic starter. Then 15 to 20 ml of rennet solution (1:10,000) is added per 100 l of milk. The temperature at addition of the rennet is between 29° and 35°C, depending on the fat content. The whole curdling time amounts to 40 to 45 minutes. The curd is cut into 1.5- to 2-cm pieces. After 10 minutes, it is cut again and after 15 minutes some whey is taken off and the coagulum is agitated for 5 to 10 minutes in order to make it somewhat firmer. The coagulum is filled into perforated molds, and then kept for 24 hours in a salt bath (16% to 18% NaCl between 16° and 18°C). The cheese is then allowed to drain and dry. It is dried for another 2 to 3 days in the ripening cellar. Then it is smeared, ie, coated with a red-smear culture (*Brevibacterium linens*). Smearing must be repeated between three and eight times, depending on the size

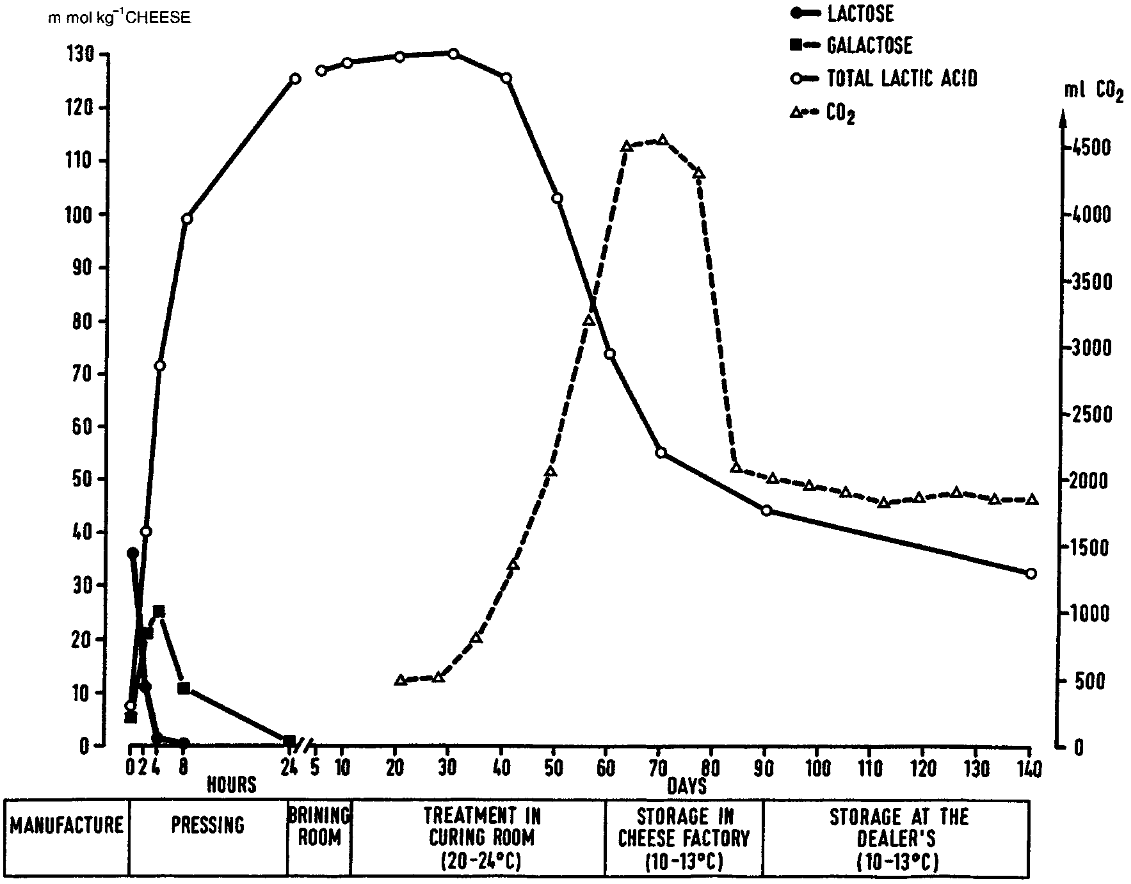

Figure 23-7 Production of Carbon Dioxide from Lactate during Ripening of Emmental Cheese. The underlying propionic acid fermentation is induced by transfer of the cheese loafs from a low temperature to the curing room at 20°–24°C. The CO_2 produced is responsible for the generation of the cheese eyes in Emmental cheese. Part of the early fermentation stage shown in Figure 23-6 is included. Courtesy of Swiss Federal Dairy Research Station, Liebefeld, Bern, Switzerland.

of the cheese, in order to obtain a thick surface growth of bacteria, particularly when the cellars are relatively dry and are at relatively high temperatures, otherwise growth of undesired molds takes place. Good ripening conditions are 14°C and a relative humidity of 90° to 95°C. After 3 to 4 weeks or, in the smaller cheeses after only 2 to 3 weeks, as soon as the red smear has developed well (Figure 23-9), the cheeses are packed in aluminum or paper foils. While in the classical cheese dairy the smearing of the surface was carried out by hand, today this task is performed mechanically. For steps in the manufacture see Table 23-10.

Camembert Cheese. This white-molded soft cheese variety is of particular interest for the cheese industry since ripening takes only 1 or 2 weeks, it can be produced in a variety of fat contents (about 20% to 65% fat in dry matter), and due to the relatively low dry matter content of soft cheese, the milk supply for the same amount of soft cheese is much lower than for a traditional hard cheese. In modern cheese technology, milk concentrated by ultrafiltration is commonly used for the manufacture of Camembert-type cheeses.[52]

Camembert is characterized by the development of the fungal mycelium at the surface and in the uppermost curd layers within the first weeks of cheese manufacture. The typical ripening progresses from the outside to the interior, induced by several proteases excreted from the mycelium. One end-product of this proteolysis is ammonia formed from deaminated amino acids. This leads to an increase in the pH value and to a characteristic smell (see *Microbiology of the Cheese Surface* in Section 23.7.2).

For steps in the manufacture see Table 23-10. Nowadays Camembert may be produced from raw milk in certain countries (eg, France), but normally

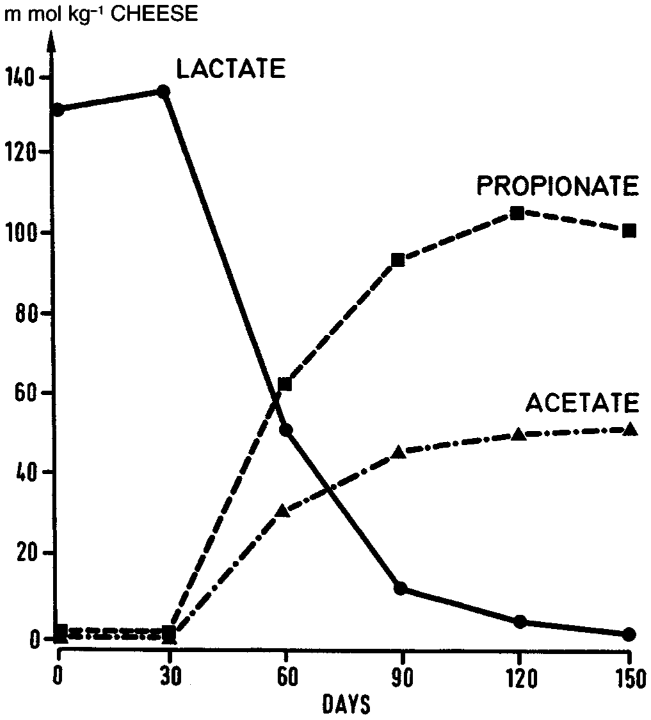

Figure 23-8 Course of the Propionic Acid Fermentation in an Emmental Cheese during Treatment in the Curing Room. Detail from Figure 23-7. Courtesy of Swiss Federal Dairy Research Station, Liebefeld, Bern, Switzerland.

from pasteurized milk. Other modern developments are the use of continuously working coagulators where the milk is curdled and the coagulum cut in an "endless" rubber trough, or the use of a thermophilic starter culture (*Streptococcus thermophilus*) instead of the traditional mesophilic cultures.[123]

Roquefort Cheese.[52] Traditional Roquefort cheese is produced from fresh raw ewes' milk in different parts of France. The average protein content of the milk is 6.5% and the average fat content is 8%. As a rule, artisanal cultures consisting of whey from the cheese production of the previous day, which contain a mixed microflora of lactic acid streptococci and lactic acid bacilli, are used as starter cultures. The optimum temperature for the growth of this culture is 35°C. *Penicillium roqueforti* is added to the cheese milk in the form of a suspension of spores. The renneting temperature is 30°C and the curdling time is 120 to 150 minutes with 25 ml of rennet (diluted 1:10,000) to 100 l of milk. The curd is cut into 1- to 3-cm cubes. During the next few hours, the curd is stirred a few times. Then it is allowed to settle and the whey is drawn off. The coagulum is filled into suitable stoneware or tinplate molds (diameter 20 cm, height 10 cm). The drainage of the whey from the molds lasts about 4 days, during which they are turned once a day. During this phase a slight heterofermentation of the lactic acid type takes place in the coagulum, which serves to create cavities for the development of the fungus. These still-soft cheeses are transported (from as far away as Corsica and the Pyrenees) to Roquefort. They are dry salted by hand with coarse sea salt in salting rooms (temperature 9° to 10°C) several times in the course of 3 to 5 days. The salt-tolerant microorganisms that develop are removed from the surface with brushes. Then the cheeses are manually or mechanically pierced with needles in order to allow access of oxygen to the mass of cheese and allow growth of the fungus. Ripening must by law take place exclusively in the natural cellars at Roquefort, which run for several kilometers through the mountain. The temperature in these cellars is constant at 7° to 10°C and the atmospheric humidity is between 90% and 100%. At first, the cheeses are stored in layers on their edges at 8° to 10°C and a relative humidity of 96% for 18 to 23 days. Yeasts and bacteria that develop on the surface of the cheeses are scraped off. After the end of this aerobic ripening, to induce the anaerobic phase, the cheeses are packed into tin foil

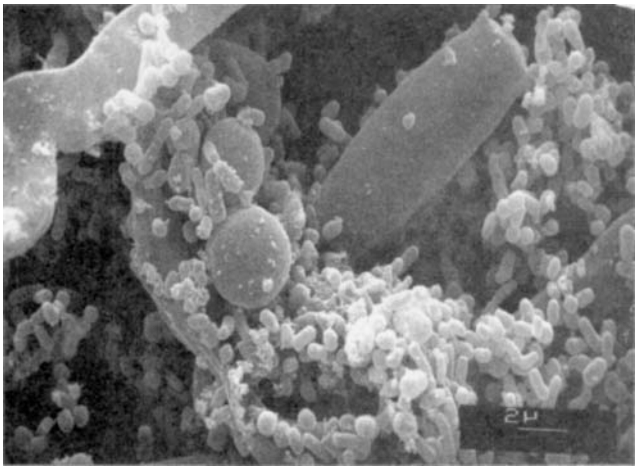

Figure 23-9 Scanning Electron Micrograph of the Surface of a Red-Smear Brick Cheese Showing Yeast Cells and Coryneform Bacteria. *Source:* Reprinted with permission from H. Neve and M. Teuber, Scanning Electron Microscopy of the Surface Microflora of Ripened Soft Cheeses, *Kieler Milchwirtschaftl. Forschungsberichte*, Vol. 41, pp. 3–13, © 1989, Bundesanstalt fur Milchforschung.

and stored at 7° to 8°C, again on their edges. Because of the lack of oxygen, the growth of the fungus slows down. Ripening, proteolysis, and lipolysis proceed further under the action of the proteolytic and lipolytic enzymes that have already been secreted into the cheese mass. This anaerobic phase lasts at least 3 months. A ripened cheese can be stored at 1°C for another 5 to 10 months. After the conclusion of ripening, the cheeses are taken from the tin foil and are packed in aluminum foil or plastic bags.

The high quality blue cheeses known in other European countries, such as Danish Blue, Bavaria Blue, and Bress Bleu, are made in a similar way from pasteurized cows' milk which, however, is otherwise treated as in the manner of Roquefort.

Mozzarella Cheese (see Table 23-10). This cheese belongs to the so-called pasta filata type which is a cheese traditionally made from raw buffalo milk.[8] Because the cheese curd is milled in hot water (80°–82°C) during the production process, a reduction of undesired microbes like enterobacteria takes place, although the time/temperature combination may not be equivalent to a true pasteurization. Modern production is mainly from pasteurized cows' milk. Remaining microbiological problems are recontamination during storage and handling in a whey-based brine.

Feta Cheese (Table 23-9). Traditional feta cheese is made from ewes' milk in Greece.[1] It has recently obtained legal protection within the European Union (EU). A similar cheese made from cows' milk must no longer be called feta. This cheese is made from a lactic acid/coagulant–produced cheese curd, which is stored in a whey/sodium chloride brine (16% to 23% NaCl) for several weeks to months. During this period, slow proteolysis and lipolysis take place yielding a typical flavor. The "ripening flora" involved is a secondary microflora containing salt-resistant species like *Enterococcus, Pediococcus,* and *Micrococcus.*

23.5 THE BACTERIOPHAGE PROBLEM IN DAIRY FERMENTATION[97,99]

23.5.1 The Extent of the Problem

Because sour milk and cheese are normally not made from sterilized milk and because most cheese fermentations are open systems (open vats, control of fermentation by direct and open inspection with hands, tools, etc), bacteriophages are a common threat. Even pasteurized milk may still contain virulent bacteriophages and residual lactic acid bacteria. The phages of the mesophilic lactococci and the thermophilic *S. thermophilus* have been investigated in detail. For the lactococci, at least 11 genetically distinct phage types have been described.[62] They may be lytic or temperate. Many starter culture strains of lactococci carry prophages that may be released during sour milk and cheese fermentations. In *S. thermophilus*, there seems to be only one genetic type of phage, which, however, reveals very distinct geographic variations and molecular specifications. The microbiology and genetics of these phages have been investigated thoroughly, leading to clear information on phage adsorption, injection, replication, and release. The host specificities have been found to vary substantially. Bacteriophage-resistant mechanisms have been characterized as being due to inhibition of adsorption, restriction/modification, or abortive infection. Many of these traits are coded for on plasmids and are therefore amenable to genetic engineering and transfers from cell to cell. In cheese factories, high bacteriophage levels in whey and curds are found under the following conditions, which may also lead to contamination with undesirable bacteria[43]:

1. Use of one centrifuge for whey and milk separation.
2. Use of whey cream for milk standardization, whey transfers by pumps, and casein fine savers in the area of raw milk silos, pasteurization equipment, and milk vacreators (gas removal devices).
3. Starter tanks located in the cheese vat room and entrance of bacteriophage to the tanks by air replacement during cooling or emptying.
4. Separate facilities for starter cans that have not been pressurized; the movement of air from whey handling areas to raw milk storage or cheese vat areas.
5. Whey stored in lines connecting vats (must be water- or air-flushed between vats).
6. Starter culture medium stored in lines connecting vats or lines from the pasteurizer and starter room. Lines should be kept at a minimum length.
7. Floor drains in the starter room (these should be eliminated) and drains in the cheese production room improperly flushed and sanitized during separate intervals of the day.
8. Improper cleaning of cheese vats between fills and lack of use of a sanitizer with at least 50 to 100 ppm available chlorine in the vat clean-in-place (CIP) system. Rinsing of vats between

refilling using whey rather than pure water contributes to a bacteriophage build-up and should be avoided.

9. Use of whey evaporator condensate or reverse osmosis permeate to wash tanks and cheesemaking equipment.
10. Use of long (excess of 1 hour) preripening times.
11. Use of non–phosphate-buffered media for bulk starter propagation.
12. Use of single-strain starter culture, if not properly protected.

In addition to the use of phage-resistant strains developed by genetic engineering or selected by challenge with bacteriophage cocktails, there are many generally accepted technological measures that reduce or avoid the bacteriophage problem. These include use of starters containing phage-unrelated or phage-insensitive strains, production of phage-free bulk starter, aseptic propagation systems, use of phage-inhibitory media, reduction of phage contamination of processing plants, starter culture rotations, air conditioning and free air flow, avoidance of aerosol generation, cleaning/chlorination of vats between refills, use of clean-in-place (CIP) systems, segregation of starter room and cheese process equipment, removal of deposits on bulk starter vessels, good factory design (suitable location of whey storage tanks, whey handling systems and wastewater treatment plants), regular use of an aerosol containing an agent such as chlorine to reduce contamination in the atmosphere, and other measures such as use of cultures for direct setting of the milk, inspection of jacket/agitators for pin holing, and early renneting.

Slow acidification due to bacteriophage attack of the starter culture may lead to good proliferation conditions for undesirable contaminant bacteria such as staphylococci, enterococci, listeria, enteric bacteria, and others. The use of strains resistant to specific phages may induce the selection of new, less virulent phages not encountered previously. The proper handling of the bacteriophage issue still remains a major challenge for proper dairy fermentations.

23.5.2 The *Lactococcus*-Specific Bacteriophages[56,132]

Bacteriophages are a common and constant threat to milk fermentation by lactococci, as most fermentations cannot be performed under sterile conditions, because heat sterilization damages the casein micelles, preventing proper coagulation and syneresis of the cheese curd. Even pasteurized milk may still contain phages and some residual lactic acid bacteria.

Hundreds of such phages have been isolated and described during the last five decades. However, only after progress in molecular biology could these phages be differentiated on the basis of DNA-DNA hybridization and protein profiles, for example. As a consequence, the International Subcommission on the Taxonomy of Bacteriophages of *Lactococcus* was able to agree on the establishment of defined bacteriophage species and type phages, which are available from an international reference laboratory.[62] The 11 defined species do not show detectable DNA homology, which is quite astonishing on the basis of the quite similar morphology especially of species commonly named "small isometric head" phages. Most of these species have been isolated as virulent or lytic phages. Only BK5-T is a temperate phage, and P335 reveals strong DNA homology with some temperate phages. Between 50% and 70% of the investigated bacterial host strains could be induced to release between one and three morphologically distinct prophage particles upon induction with mitomycin C or UV irradiation. Isolation of prophage-cured strains, however, is extremely difficult, because of immediate relysogenization of the cured derivatives in the induction assay. By electron microscopy, at least 19 morphologically distinguishable prophage particles have been detected. The taxonomic diversity of the lactococcal bacteriophages suggests, together with the observed diversity of lactococcal strains in mixed-strain starter cultures, a long and rapid evolution.

Biology of Host-Virus Interaction

Typically, milk to be fermented with *Lactococcus* is seeded with about 10^7 cfu ml^{-1}, which grow up to about 5×10^9 cfu ml^{-1} at the end of fermentation. Nine cell divisions will yield this increase. If only half of the world's cheese production is assumed to be manufactured with lactococci (ie, 7 million tons or 7×10^9 kg) this corresponds to 7×10^{10} liters of milk inoculated with about 10^{21} cfu proliferating to 10^{23} viable bacteria every year. Because cheese whey from a mixed-strain fermentation typically contains 10^6 to 10^8 phage particles ml^{-1} (even in the absence of a noticeable phage attack), up to at least 10^{21} phage particles are released during roughly 10^{22} cell divisions. This again provides ample opportunities for evolution of bacteria and phages.

Phage adsorption is usually not equally and densely packed over the whole bacterial cell surface, but to a few specific spots at the surface, possibly in the vicinity of the plane of cell division.[13] For that reason, the biochemical identification and isolation of phage receptor molecules has not yet been successful, although membrane lipoteichoic acid, cell-surface galactose- and rhamnose-containing polysaccharides, and murein complexes have been suggested to participate in phage adsorption. Latency periods after infection are around 90 minutes and burst sizes between 10 and 100 per infected cell.[99]

Most isolated virulent phages are very specific for a limited number of strains; a few, especially the prolate-headed phage species c2, may even cross the subspecies line between "lactis" and "cremoris." In addition, bacteria infected and lysed by such phages produce a highly active bacteriophage-coded lysin, which is able to lyse lactococci from the outside even if the strain is resistant to phage adsorption. For temperate phage particles released by mitomycin or UV induction from isolates from a mixed-strain starter culture, it is difficult to find sensitive host strains in that and in other starter cultures.This may reflect in part the situation that prophage-sensitive bacterial strains are immediately and constantly eliminated in a starter culture either by lysis or by lysogenization. *Lactococcus lactis* subsp. *cremoris* Wg2, a strain well known from investigations of the plasmid-coded cell wall–protease system, is exceptionally susceptible to many prophage particles (because of lack of a restriction/modification system?).

Distribution of Bacteriophage Resistance

When single isolates (23 each) of three undefined mixed starter cultures (A, B, C) were tested against 375 phage strains from our collection, only 34 phages, that is, fewer than 10%, showed lytic activities against one or more of the 69 bacterial strains. In all, 9 bacterial strains from culture A, 14 from culture B, and 2 from culture C were susceptible to one or more phages, the highest sensitivity being one bacterium from culture A, which was sensitive to eight different phages.[14] This observation suggests that phage-host interactions are rather specific. This is also evident from the specificity of phages isolated during the application cycles of the three starter cultures in a cheese factory. The phages appearing during cycle A were mainly specific for bacterial strains from culture A, and likewise for the cycles B and C. The distribution of strains with varying degrees of phage resistance in four different, undefined mixed-strain starter cultures is remarkable. A significant individual resistance level is evident. From a total of seven undefined mixed-strain starters, 30 permanently and highly phage-resistant strains were obtained by challenging with a phage cocktail containing all phages ever isolated in the author's laboratory.[93] This proves the high potential of lactococci to develop phage-resistant mechanisms, which actually allowed the successful use of such bacteria in spontaneous milk fermentations during the hundreds of years before the invention of starter cultures 100 years ago by Weigmann and others.

If the spatial distribution of phages in dairy plants is investigated, high numbers are found in whey and in the product (if it is not pasteurized). After enrichment, phages are detected in raw and pasteurized milk, on the surface of equipment, the clothes and skin of the cheese makers, and in the air, especially in the neighborhood of areas where whey-containing aerosols are produced, for example, close to whey separators. Cold disinfection of phage-contaminated surfaces and material is most effective with hypochlorite and peracetic acid.[76]

Mechanisms of Bacteriophage Resistance

Restriction of bacteriophages can be demonstrated commonly in lactococci, eg, with host-virus systems isolated from cheese factories. The observed efficiencies of restriction in plaque numbers are between 10^3 and 10^7. In addition, inhibition of phage adsorption has been reported quite regularly. However, because phage adsorption to lactococcal cells is difficult to determine and to distinguish from unspecific binding, due to the "hot-spot" mechanism, adsorption studies can only be trusted if controlled by electron microscopy. The most interesting phenomenon is the quite common effect of "abortive infection." This has been demonstrated unequivocally by the proof of phage adsorption and DNA-injection with phages carrying a genomic DNA labeled with the fluorescent dye DAPI.[49] In some systems, phage replication is inhibited as late as in the translation of phage messenger RNA into phage protein.

Plasmids and Bacteriophage Resistance

Plasmids are common in lactococci as discussed above. In ecological terms, lactococci are able to exchange genes necessary for better survival in milk. Phage-resistant plasmids of lactococci have been characterized and some of the genes coding for phage resistance have been cloned. In addition, phage-resistant plasmids have been transferred by conjugation to phage-sensitive starter culture strains. In the dairy industry in the US, use of strains showing resistance to phage species c2 and 936 has led to the enrichment of phages from the P335 species in

American dairies. These newly isolated phages (known in Europe for some time) had high numbers of restriction sites in their genome in contrast to the traditional c2 and 936 phage species. This observation is suggested to result from a selection during evolution for phage strains with no or few restriction sites, which are therefore able to escape the restriction/modification systems of lactococci.[92]

Molecular Biology of Lactococcal Bacteriophages

The study of the molecular biology of the bacteriophages of lactococci is in a rapidly developing stage. All phages hitherto isolated contain double-stranded DNA in a closed circular, linear, or permutated form. In terms of DNA sequences, we know the nucleotide sequences of a gene coding for a presumptive structural protein and of the structural gene for lysin in prolate-headed lactococcal bacteriophages of the c2 species. Several more or less strong promotors have been isolated from lactococcal phages with the use of promotor probe vectors. Some work has been done regarding the integration of temperate phages into the lactococcal chromosome. Also, the characterization of restriction/modification systems involved in phage resistance is in an early phase. An interesting approach is the use of antisense mRNA to induce bacteriophage resistance in lactococci.[71] Some genomes of temperate and lytic phage have recently been sequenced completely, allowing further insight into replication and integration of these phages.

Stability of Bacteriophage Resistance in Lactococci

The fact that many resistance phenomena are coded for on plasmids suggests that plasmid loss could lead to loss of phage resistance, which is indeed the case. In everyday cheese making, the loss of phage resistance of undefined mixed-strain cultures was unequivocally shown by the experience of Stadhouders and Leenders[126] in the Netherlands. As soon as the cultures were propagated in the laboratory in sterile skim milk in the absence of phages, the mixed-strain cultures were converted into a culture with just a few dominating strains. The previously high bacteriophage resistance, known from cheese fermentations, was completely lost within a short time. This observation emphasizes the need for a constant challenge to such cultures under manufacturing conditions in order to keep them in an optimal state.

23.6 FERMENTED DAIRY PRODUCTS CONTAINING "PROBIOTIC" MICROORGANISMS

The health significance of living microorganisms in fermented dairy products is most controversial at this time. It is discussed with passion by the scientific community, but also within the International Dairy Federation and the corresponding trade associations within the EU.[59,133]

The background is the fact that the traditional, spontaneously fermented dairy products contained living microorganisms that proliferated during fermentation. Induced by the concept of Metchnikov at the beginning of this century, people started to believe that living lactic acid–producing bacteria consumed with fermented dairy products (yogurt, kefir, sour milk) would have a beneficial effect on the intestinal microflora of man and animals. The mechanisms of action suggested were twofold: (1) the ingested microorganisms attach to the intestinal mucosa thereby displacing harmful bacteria, and (2) the ingested microorganisms multiply and produce inhibitors, which induce a decrease of harmful microorganisms or inhibit their multiplication and increase. There are a number of obstacles to this general belief. First, the lactic acid bacteria used for dairy fermentations are not members of the normal intestinal microflora. They are best adapted to their substrate, milk; they are not adapted to the substrates and environment present in different segments of the intestine. The intestinal sites are already populated by bacteria best adapted to them (eg, up to 10^{12} g^{-1} feces). It is almost impossible to invade such a crowded biotope successfully.[46] Components of the microflora of fermented dairy products have been shown to appear transiently at low numbers (10^3 to 10^5) in the feces as long as the fermented product is consumed regularly.[7,89] Experiments with enteropathogenic *Escherichia coli* strains given to volunteers together with or without fermented products containing *Enterococcus faecium* SF68 (Table 23-13) clearly showed no protection against enteropathogenic *E. coli* by the fermented products.

The obvious inability of *Streptococcus thermophilus*, *Lactobacillus delbrueckii* subsp. *bulgaricus*, and *Lactococcus lactis* to establish themselves in the intestinal microflora of man and animal, led the supporters of Metchnikov's ideas to incorporate probiotic members of the intestinal microflora such as bifidobacteria, *Lactobacillus acidophilus*, *Enterococcus faecium*, and some other lactobacilli into fermented dairy products. The problem arose that these

Next Page

bacterial species are not well adapted to milk as substrate. This can be overcome by adding separately cultivated bifidobacteria and *Lactobacillus acidophilus* in high numbers to the milk before fermentation into sour milk, yogurt, and cheese.

The term *probiotic* was originally used to denote substances secreted by a microorganism that stimulate the growth of another, in contrast with the traditional definition of an antibiotic. Finally, Fuller[47] redefined probiotic as "A live microbial feed supplement which beneficially affects the host (animal) by improving its intestinal microbial balance." This definition has the following weak points, which still contribute to the scientific and public confusion regarding probiotics: (1) The beneficial effect can be interpreted so broadly that almost everything fits into it, (2) improving of a balance is not possible in a logic sense; therefore, some authors use the term *stabilization,* and (3) the intestinal microbial balance is not known for any individual human or animal being. It may be the situation when the individual feels healthy regarding its digestive function.

This lack of a clear definition has led to the situation in which lists of beneficial functions derived from the properties of probiotic microorganisms have been produced. The main contrast with traditional starter cultures is the fact that probiotic cultures have no function in the fermentation of the product but are claimed to have a function in the body of the consuming macroorganism. Table 23-12 lists the desirable properties of probiotic bacteria.[75]

The following probiotic microorganisms are used in some products that are on the market:

1. Several *Bifidobacterium* species (*B. longum, B. infantis, B. bifidum, B. breve, B. animalis, B. lactis*)
2. Several *Lactobacillus* species (*L. acidophilus, L. casei, L. delbrueckii* subsp. *bulgaricus, L. plantarum, L. reuteri, L. rhamnosus*)
3. *Enterococcus faecium*
4. *Propionibacterium freudenreichii*
5. *Saccharomyces boulardii*

Some of these microorganisms, if consumed with fermented dairy products, were found transiently in the intestinal microflora of human volunteers (up to 10^3 to 10^5 g^{-1} feces), but normally not exceeding the number of the naturally occurring related bacteria in the autochthonous flora of the consuming individual.

Recent research has concerned the prevention and treatment of diarrhea and urinary and vaginal infection. Results are controversial and inconclusive (Table 23-13).[34] There seems to be some protective effect in the treatment of diarrhea; it is, however, not possible to predict whether a specific person will benefit from the treatment.

The following additional claims are made for the beneficial effects of fermented dairy products generally, and bifidus and acidophilus products in particular on the consumer: (1) cultured products with living probiotic bacteria enhance the growth of young animals, and may protect them against dysenteries, (2) lactose digestion may be enhanced, which may be important for lactose-intolerant persons, (3) mineral (calcium) absorption might be increased, (4) the cholesterol level of blood may be reduced, (5) the ingested microorganisms colonize the gut, lower intes-

Table 23-12 Desirable Properties of Probiotic Bacteria

Health and Clinical Properties	*Stability and Technical Properties*
Human origin	Ability to maintain verified viability
Resistance to acid and bile	Maintenance of good flavor and aroma profile after fermentation
Adherence to human intestinal cells	Maintenance of mild acidity throughout storage; good acidity profile
Colonization of the human gut	Maintenance of colonizing properties throughout processing and storage
Production of antimicrobial substances	Development of good storage stability in fermented products
Antagonism against cariogenic and pathogenic bacteria	Stability after freeze drying and other drying methods
Safe for human consumption	Accurate identification of strains
Clinically validated health effects	Dose-response data for required effects

tinal pH, adhere to the intestinal walls thereby preventing colonization by pathogens, compete for nutrients with pathogenic bacteria, produce antibacterial substances, and neutralize toxins, (6) cultured products have antitumor and antimutagenic properties, (7) cultured products interact with the immune system, and (8) relieve constipation, reduce transit time, and increase stool frequency.

It must be stated clearly that many of these claims could not be verified when the experiments were repeated by other laboratories, with other animals or persons, and with different products. The only generally accepted result seems to be the observation that lactose-intolerant persons are able to digest lactose properly if it is consumed in the form of yogurt. Sometimes this effect was only observed if living bacteria were present; sometimes the same effect was also seen with pasteurized yogurt.

Although a 400-page book was published on this subject[47] careful reading reveals that the book mainly describes problems and not solutions. In my opinion, we do not know enough about the intestinal microflora to be sure that consumption of fermented dairy products containing living bacteria does improve the microbial balance of our gut, whatever that means. Whereas we have a great deal of information regarding the microbiological and biochemical composition of fermented dairy products, most of the claims regarding "probiotic" action inside our body still remain fiction and wishful thinking.

That the administration of different *Lactobacillus* strains may indeed lead to *in vivo* colonization of the human intestinal mucosa was recently shown in a very controlled study where the bacteria were given in the form of fermented oatmeal soup. This study investigated the microflora of the intestine by taking biopsy samples from the upper jejunum and the rectum. Of the 19 tested bacterial strains, only 5 strains could be reisolated from the mucosa samples. The administered *Lactobacillus acidophilus* strains were not detected.[64] Only very few of the dairy strains have been tested with such an elaborate method, although they are added to many products. Further research is needed to assess the claims for probiotics.

Until this has been achieved, the summary statements of the very careful and critical review of Marteau and Rambaud[89] are still a valid description of the current situation: "There is in 1993 no proven medical indication of lactic acid bacteria for therapy or immunomodulation in man."

There are recent claims that specific "probiotic" bacteria induce a nonspecific stimulation of the human immune system such as increased IgA excretion after immunization with a *Salmonella* vaccine or increased phagocytosis of *E. coli* by certain phagocytes circulating in the blood. However, a control with ordinary yogurt has not been done.[83]

An exciting development is the use of lactic acid bacteria (ordinary lactococci and lactobacilli) as vaccine delivery systems. The first successful experiments in animals prove that such bacteria, live or dead, interact with the intestinal immune system, eg, protecting mice against tetanus toxin.[144]

These observations must be taken as an indication that possibly many bacteria, if not all, that are consumed with food could interact with the GALT (gastrointestinal associated lymphoid tissue). Therefore great care must be taken when applying new "probiotic" bacteria as a high level food supplement.[90] In summary, the following points must be observed if the "probiotic" concept is to be validated:

1. We need a clear, logical new definition.
2. We need a clean and thorough taxonomy of all the 400 to 600 different species suggested to grow in the human intestine, including the not-yet-culturable species.
3. We need to know the qualitative and quantitative distribution of microorganisms in the longitudinal (duodenum, small intestine, colon) and cross axis (mucosa, lumen) of the intestine.
4. The metabolism of food components *in situ* must be studied in the different sections of the intestine defined in point 3 above.
5. We are only at the beginning of understanding the immune system and its function in the intestine. We do not know much about the tolerance of the human body against its normal microflora. We know even less what happens if we introduce new "probiotic" bacteria. For example, the possibility of an anaphylactic event in probiotic-induced individuals has not been investigated.
6. We know too little about the influence of a normal diet and all its components on the intestinal microflora. The possibilities must be investigated that the changes attributed to application of probiotic bacteria might be obtained by stimulating specifically, for example, bifidobacteria, lactobacilli, or others, with specific food ingredients ("prebiotics").
7. We need more controlled and independent clinical research in addition to the basic microbiological problems still at hand.

23.7 THE MICROBIOLOGICAL SAFETY OF FERMENTED DAIRY PRODUCTS

23.7.1 Safety of Sour Milk Products

It is now common worldwide to produce yogurt, sour milk, sour cream, and fresh cheese from pasteurized milk. Because milk that has been properly pasteurized (see Codex Alimentarius) poses no health risks for the consumers, fermented milk products have the same safety level if post-pasteurization recontamination is prevented. Because of the lowered pH of fermented milk, the main risk is the growth of contaminating yeasts and molds. One contaminating yeast cell in a 250 g fresh cheese pack can multiply to 10^4–10^6 cfu g^{-1} within a storage period of 15 to 20 days at 5° to 10°C.[35] However, modern aseptic fermentation and packaging procedures are available to avoid contamination by yeasts and molds. Yeast spoilage is recognized by the consumer because of its "yeasty" taste and smell but it poses no health hazard. The development of visible mold growth on the surface of fermented milk products leads to rejection of the product. There is a need that fruit, nuts, and other ingredients added to sour milk, yogurt, or fresh cheese are themselves microbiologically safe to avoid hazards like the contamination with *Clostridium botulinum* toxin in a recent incident in Great Britain (Chapter 41).

23.7.2 Safety of Cheese

Outbreaks of Foodborne Illness Associated with Cheese

Table 23-14 lists the main outbreaks of foodborne illnesses associated with cheese that have been

Table 23-14 Reported Outbreaks of Foodborne Disease Associated with Cheeses Since 1980

Outbreak	*Pathogen*	*Number of Cases*	*Number of Deaths*	*Food*	*Reference*
1980, England and Wales	*Salmonella sp.*	6	NR	"untreated" goats' milk cheese imported from Turkey[a]	122
1980, US	*S. heidelberg*	>339	NR	cheddar cheese[b]	33, 44
1981, Italy	*S. typhimurium*	>100	0	mozzarella cheese[b]	53, 122
1982, Canada	*S. muenster*	NR	NR	cheddar cheese[c]	33, 146

[g] Four reported cases of hemolytic uremic syndrome (HUS).

[h] One case of hemolytic uremic syndrome.

documented in the literature for the period starting in 1980. A discussion of the safety of cheese was published recently.[58] Although cheese consumption amounts to at least 15 million tons of cheese per year in the world,[61] the reported rate of cheeseborne illness must be regarded as relatively low. On the other side, the recorded incidences include pathogenic bacteria such as *Clostridium botulinum, Listeria monocytogenes, Salmonella,* and *Brucella* species. As a consequence, cheese producers must aim at a further and constant watch of the hygienic conditions in cheese manufacture.

Microbiological Risks

Soft and semi-hard cheeses with a high water activity (Table 23-11), especially when made from raw milk, need extra attention including investigation of the presence of antibiotic-resistant bacteria. Post-pasteurization contamination is the main risk of cheeses made from properly heat-treated milk. It must be recognized, however, that cheeses made from raw milk present the main sources of cheeseborne outbreaks. One reason is surely the fact that soft cheeses do not provide sufficient hurdles (pH value, water activity) to prevent the growth of pathogenic bacteria once they have contaminated or recontaminated the cheese milk and the cheese itself. In hard and semi-hard cheeses, there may be an inhomogenous structure with no regular distribution of water content or lactic/propionic concentration allowing the growth of undesired microorganisms in such niches. The cheese rind as a natural cover (see below) is another microbiological problem.

Obviously, the microbiological safety of cheese cannot be properly controlled if raw milk or thermized milk is used rather than pasteurized milk. Other methods of reducing the microbial load of raw milk like bactofugation, microfiltration, or use of additives (H_2O_2 and catalase, or carbon dioxide), do not achieve the same effect as pasteurization by heat. It is important to prevent post-pasteurization contamination, which may result in survival and growth of pathogens during manufacture and ripening of cheese. The risks of pathogens in cheese have been assessed into high, medium, and low risk categories.[65–67]

High Risk

- *Salmonella* species: Involved in several cheese outbreaks; widespread in environment, low infectious dose, some heat-resistant species. Survives in cheese.
- *Listeria monocytogenes*: Involved in several outbreaks associated with soft or soft-ripened cheese; grows at refrigeration temperatures; survives in Cheddar and Colby, multiplies in cheeses such as Brie and Camembert.

- Enteropathogenic *Escherichia coli*: Involved in soft-ripened cheese outbreaks. Very virulent. Also verotoxigenic (enterohemorrhagic) *E. coli* (eg, *E coli* O157:H7); important emerging pathogen.

Medium Risk

- *Streptococcus* (Group A): Can cause mastitis; very virulent; survives in cheese.
- *Streptococcus* (Group C): Caused milkborne outbreaks. Can cause mastitis.
- *Brucella abortus*: Can cause mastitis; relatively heat insensitive, but eliminated by pasteurization.
- *Mycobacterium bovis*: Can cause mastitis; relatively heat insensitive, but eliminated by pasteurization.
- *Pseudomonas aeruginosa*: Opportunistic pathogen.
- *Coxiella burnetii*: Can cause mastitis; relatively heat insensitive, but eliminated by pasteurization.
- *Vibrio* species: Potential pathogen.
- *Aeromonas hydrophila*: Potential pathogen; predominantly aquatic.

Low Risk

- *Staphylococcus aureus*: Control measures effective and well-known.
- *Clostridium botulinum*: Control measures effective and well-known.
- *Clostridium perfringens*: No known outbreaks associated with cheese.
- *Corynebacterium diphtheriae*: No known outbreaks associated with cheese.
- *Bacillus cereus*: No known outbreaks in cheese.
- *Campylobacter jejuni*: No known outbreaks in cheese. Apparently does not survive in cheese.
- Viruses—hepatitis A, polio, retrovirus, coxsackie, adenovirus, herpes, oncogenic, foot and mouth disease: Known to contaminate milk. Transmission modes and heat resistance not understood.

Of the high risk pathogens, *Listeria monocytogenes* (though known in veterinary and medical bacteriology for decades) can be regarded as a recently emerged pathogen in dairy microbiology due to prolonged ripening and storage of cheeses at low temperatures (around 5°C), which favors proliferation of this psychrotrophic species. Because the species is quite ubiquitous, occurring in plant material, silage, raw milk, feces, and meat, it enters the cheese factory not only with raw milk but with diverse organic material. Especially soft and semi-soft cheeses with a bacterial or mold surface microflora (smear) are sensitive to recontamination and proliferation. *Listeria monocytogenes* must be absent from the environment of cheeses (vat, brine, cheese brands, smear, flavor, sinks, wells) and the cheese factory in order to produce a *Listeria monocytogenes*–free cheese.

Spahr and Url[124] have compiled data (Tables 23-15 and 23-16) on the experimental behavior of *L. monocytogenes* during cheese manufacturing and cheese ripening. In general, *Listeria* does not grow during the ripening period in semi-hard and semi-soft cheese without smear ripening, and numbers tend to decrease. The final *L. monocytogenes* concentration is in the same order of magnitude as in the initial milk. In smear-ripened cheese, however, a marked increase in *Listeria* counts occurs on the surface of contaminated cheeses. *L. monocytogenes* was reported by Ryser and Marth[115] to multiply in the interior of Camembert cheese. It should be noted that the survival time for *Listeria* was less than 1 day in experimental production of hard cheeses (Emmental, Gruyère) with cooking temperatures well above 50°C. In Parmesan, *Listeria* is dead before the official end of the ripening period. If a cheese like mozzarella is pasteurized after fermentation, *Listeria* are destroyed. All other cheese types such as semi-hard cheeses have rather long survival times for *Listeria* and must not be contaminated during manufacture and ripening.

Salmonella viable counts, like those of other pathogens increase by about one order of magnitude during cheese manufacture, but decrease again during cheese ripening (Table 23-17). Die-off is slower at the low ripening temperatures. These do not permit proliferation of *Salmonella* on the cheese surface or the interior.

In general, *E. coli* counts show a remarkable increase during the manufacture and ripening of cheese (up to three orders of magnitude). Finally, a decrease is observed (Tables 23-18 and 23-19).

In hard cheese, *Yersinia enterocolitica* is able to survive for periods of more than 56 days, whereas in feta cheese its behavior is severely influenced by the pH value of the cheese demonstrating an acid sensitivity (Tables 23-18 and 23-19).

Campylobacter jejuni is likely to be destroyed rapidly once the pH value decreases below 5.0 as in cottage cheese. No survival was observed in cheddar cheese after 15 days of ripening.

Brucella abortus counts decrease during the manufacture of cheese as well as during subsequent

ripening. Survival time from an inoculum of 10^4 cfu ml^{-1} of milk was 6 days in hard cheeses and 10 to 17 days in soft cheese.

Staphylococcus aureus (besides *Salmonella*) has been the most prominent food poisoning agent in raw milk and recontaminated pasteurized milk cheeses because of the following reasons:

1. Contamination of raw milk during milking from the udder surface is inevitable.
2. In the case of *S. aureus*-induced mastitis, the bacteria are shed into the milk.
3. *S. aureus* is well adapted to a low water activity, eg, in salted cheese.
4. *S. aureus* is able to tolerate moderate lactic acid concentration as present in cheese.
5. *S. aureus* can multiply to high numbers during cheese manufacture and ripening in soft and semi-hard cheeses. In hard cheeses (Tables 23-20 and 23-21), a trend to survival, but decrease during ripening is evident.
6. *S. aureus* can produce enough enterotoxins in cheese to cause acute food poisoning.
7. *S. aureus* enterotoxin survives for months in cheese even if the viable counts decrease.

The only safe measure to avoid *S. aureus* in cheese is the use of pasteurized milk and control of post-pasteurization recontamination. Although *S. aureus* food poisoning is not a life-threatening disease, people feel very sick and will most likely not buy the incriminated cheese again.

Microbiology of the Cheese Surface

Like fermentation in the cheese interior, the microbiological processes occurring at the surface of cheese during manufacture, ripening, and storage of cheese must be considered as a solid-state substrate fermentation. The problem starts with the definition of the surface (only the microbial biofilm or in addition the uppermost 1 to 5 mm of the solid substrate?). In order to describe the entire system (biofilm and substrate), a practicable definition of the cheese surface is proposed as the uppermost layer of cheese (up to 5 mm) including the surface biofilm. By this definition, it is possible to describe the dynamic changes of the sur-

face microflora and the resulting biochemical changes in the cheese matrix.

The traditional use of spontaneous surface fermentation has been replaced by the use of specific starter cultures (molds, yeasts, and coryneform bacteria), which are either added to the cheese milk or applied during ripening by regular smearing of the cheese surface with a proper bacterial/yeast culture.

Surface of Brick Cheeses. It is generally assumed that initially a yeast microflora has to degrade some of the lactic acid of the primary lactic fermentation in order to allow growth of the more neutrophilic coryneform bacteria. A recent investigation of surface-ripened brick cheeses (Limburger, Romadour, Tilsiter, Münster, Weinkäse, and Harzer[140]) using undefined ripening cultures found *Debaryomyces hansenii* and *Galactomyces geotrichum* prevalent in rennet cheeses (Table 23-22), and *Kluyveromyces marxianus* and *Pichia membranaefaciens* in acid-cured cheese. The coryneform bacteria that followed were identified as *Arthrobacter nicotianae, Brevibacterium linens, Corynebacterium ammoniagenes, Corynebacterium variabilis*, and *Rhodococcus fascians* (Table 23-23). However, about one-third of the isolated strains could not be determined down to the species level. It is hoped to develop from these cultures a suitable starter culture.

Another problem of these surface-ripened cheeses is the growth of Gram-negative bacteria of probable enteric origin if raw milk was the substrate of cheese making. However, if pasteurized milk is used, lactose-positive Gram-negative bacteria will still be present. Presumably, this is due to post-processing contamination. Figure 23-10 shows the development of the surface microflora of a soft cheese made from pasteurized milk with a defined yeast/*Brevibacterium* starter culture. The flora grows up from a low number to take over the dominant role. The Gram-negative bacteria identified out of 169 isolates in-

cluded 23% *Klebsiella oxytoca,* 7% *Klebsiella pneumoniae,* 1% *Klebsiella ozaenae,* 19% *Serratia liquefaciens,* 4% *Citrobacter freundii,* 7% *Enterobacter agglomerans,* and 3% *Enterobacter cloacae.* Of the isolates, 29% could not be identified with the API 20E system.

A preliminary analysis of 18 other surface-ripened cheese types including Appenzeller, Tilsit, Tête de Moine, Romadour, and others showed a similar Gram-negative surface flora. However, prominent species on the surface of some semi-hard cheeses were *Proteus vulgaris, P. rettgeri, P. stuarti, Morganella morganii,* and *Hafnia alvei.* Obviously, surface-ripened cheeses do contain Gram-negative bacteria. Their interpretation as fecal coliforms is questionable because many of these species also occur in other environments including soil, water, and plants. The fact that some of them are regarded as opportunistic pathogens has to be considered if a diet for immuncompromised persons is proposed.

Surface of Mold-Ripened Cheeses (Camembert and Brie[110]). The main hurdles regarding microbiological safety of cheeses are their water activities and their pH values, ie, their organic acid contents. These hurdles are high in hard cheeses, but tend to disappear in soft cheeses during ripening (Table 23-11). The surface flora of *Penicillium camemberti/caseicolum* developing together with certain yeasts during the first week of ripening leads to a degradation of lactic acid. Together with proteolysis and the resulting products (peptides, amino acids, NH_3), this

induces an increase of the surface pH values from about 4.5 right after the end of the lactic fermentation to well above 7, and to about 6 in the cheese interior after 3 to 4 weeks of ripening.[78] Prolonged ripening of 60 days may produce an interior pH of >7.[115] Because the water activities of mold-ripened cheeses like Camembert and Brie (a_w 0.97 to 0.98) are also high, there is little or no barrier to prevent growth of undesired microbes if they should be present due to primary (raw milk, see below) or secondary contamination during manufacture. Because raw milk cannot be produced with the necessary low microbiological risk, many countries prescribe that pasteurized milk must be used for the production of soft cheeses. The prominent listeriosis outbreaks from cheese in Europe were all caused by contaminated soft cheeses made with unpasteurized milk (Table 23-14). Recent microbiological analysis of European soft cheeses made from raw milk demonstrated that about 50% of them were contaminated with *Listeria* and/or *Escherichia coli*.[41] Another hazard of raw milk soft cheeses is the presence of antibiotic-resistant enterococci and staphylococci. The Gram-negative microflora of such soft cheeses is very similar to the one described above for surface-ripened brick cheeses.[94] Although pasteurization of milk eliminates foodborne pathogens, a low level of Gram-negative bacteria can only be obtained with cheeses made from pasteurized milk if post-pasteurization recontamination, eg, by the cheese makers, the process water, the rennet preparation, or the equipment is prevented.

A recent analysis[30] of raw milk from 27 selected farms delivering milk for raw milk Camembert production revealed that the predominant bacteria were *Pseudomonas* (2000 cfu ml^{-1}), lactococci (760 cfu ml^{-1}), and Micrococcaceae (720 cfu ml^{-1}). Lactic acid bacteria were detected in all samples. Coliforms were present in most samples, but 84% had counts below 100 cfu ml^{-1}. *Staphylococcus aureus* was detected in 62% of milks (average 410 cfu ml^{-1}), *Escherichia coli* in 80% (less than 10 cfu ml^{-1}), *Clostridium perfringens* in 100% (but less than 1 cfu ml^{-1}). During 6 months, 2 of the tested milk samples were positive for *Salmonella* (2.9%), 4 for *Listeria monocytogenes* (5.8%), 25 for *Yersinia enterocolitica* (36%, the proportion of pathogenic strains being probably low), and 1 for *Campylobacter* (1.4%). Because the milks of different farms are mixed in cheese factories, even a low percentage of contaminated milk samples will spoil the whole lot used for raw milk cheese production. This means that the seemingly low risks on a farm basis are unpredictably multiplied by the practice of bulking milk. These investigations, in this author's eyes, are a further strong argument for the use of pasteurized milk for soft and even semi-hard cheese production.

23.7.3 Biogenic Amines in Fermented Dairy Products and Cheeses

Biogenic amines are typical metabolites found in fermented food and fodder[9] including beer, wine, cheese, fermented raw sausage and meat, and silage. They are the decarboxylation products of amino acids released from food proteins due to enzymatic hydrolysis, eg, during cheese ripening. In cheese, it is mainly the contaminating or autochthonous microflora, and not the starter culture, that has high decarboxylating activities. Active bacteria in this respect are certain lactobacilli like *Lactobacillus buchneri*, pediococci, and enterococci. Special attention should be directed to the Gram-negative microflora of the cheese surface (*Serratia, Klebsiella, Enterobacter,* and *Proteus* species) with a high potential for putrescine and cadaverine production in addition to histamine and tyramine. Raw milk products with a long ripening time are especially prone to develop high amine concentrations (Table 23-24).

There is no general information about the quantity of biogenic amines a person has to consume to show typical symptoms of amine poisoning. The reported examples of such outbreaks due to cheese are scarce and involve one each in 1967, 1976, 1977, 1980, and 1994 in Holland (Gouda), California (Swiss cheese), France (Ceshire), Canada (Cheddar), and Germany (Emmental), respectively, and include cheeses made from raw as well as from pasteurized milk. In the case of the Emmental, the remaining cheese was found to contain 619 mg histamine, 456 mg tyramine, 1500 mg cadaverine, and 424 mg putrescine kg^{-1}. An outbreak with 38 cases in Washington (Swiss cheese) in 1976 was obviously due to histamine levels well above 1000 mg kg^{-1}, and an outbreak in New Hampshire (Swiss cheese) was caused by similar histamine levels. In summary, the presence of amines in cheeses has to be expected. However, the actual levels depend on the type of cheese and the chances of secondary microbial contamination, in the case of cheese made from pasteurized milk, or the endogenous microflora of raw milk in the case of cheeses made from raw milk. Judging from the low number of cases reported in the literature, the risk of amine poisoning due to consumption of cheese is low. The investigated starter cultures of lactic acid bacteria used by the dairy industry have no potential to form biogenic amines.[129]

23.7.4 Antibiotic-Resistant Bacteria in Cheese

Antibiotic-resistant bacteria are becoming an increasing threat to the treatment of almost all bacterial diseases of man and animals. Humankind is approaching a self-made or at least self-induced crisis in antibiotic resistance.[15,25,95,145] For several reasons, this may become also a problem for the food industry:

1. Food of animal origin (milk, meat, and eggs) is produced from antibiotic-treated animals. Antibiotics are routinely used, for example, to treat or prevent mastitis in dairy cows, to fight intestinal and respiratory infections in calves, pigs, and chickens, or to induce a nutritive effect with subtherapeutic levels of antibiotics. It is estimated that about half of the total amount of antibiotics produced worldwide is used in agriculture.[79]
2. Some of the bacteria occurring in food and hitherto regarded as harmless contaminants have developed into important pathogens especially in nosocomial (hospital-induced) infections, including enterococci, coagulase-negative staphylococci (CNS), and certain opportunistic enterobacteria like *Klebsiella, Enterobacter, Proteus,* and *Serratia* species. Such bacteria are not uncommon in raw milk cheeses and the cheese surface flora (see above).
3. Selection and proliferation of antibiotic-resistant bacteria in the food-producing animals and the raw material derived from them may lead to direct contamination or recontamination in the

case of nonpasteurized or unheated raw material (milk for cheeses, meat for sausages) or pasteurized or thermized products, respectively.

4. Transfer of antibiotic resistances, via conjugative plasmids or transposons, between members of the microflora of food and potentially pathogenic bacteria has recently been documented *in vitro*.[137]

For example, multiply resistant enterococci and staphylococci have been isolated without difficulty from raw milk cheeses and raw cured sausages (Table 23-25). Enterococci numbered between 10^2 and 10^7 g^{-1} in cheeses and between 10^2 and 10^5 in sausages, staphylococci between 10^2 and 10^5 in cheeses, and 10^3 and 10^6 in sausages, respectively. Antibiotic resistances included resistance to penicillin, cefalotin, chloramphenicol, kanamycin, streptomycin, gentamicin, tetracyclines, fucidin, erythromycin, rifampicin, lincomycin, vancomycin, and norfloxacin in enterococci and resistance to erythromycin, tetracycline, gentamicin, chloramphenicol, rifampicin, penicillin, neomycin, and lincomycin in staphylococci. About 15% of the isolated enterococcal strains could transfer their antibiotic resistances to other Gram-positive species with the aid of conjugative plasmids and transposons. Some characteristic resistance genes were identified on a molecular level to be similar or identical with genes known from pathogenic human strains (eg, *tetM, tetS, tetK, ermAM, linA,* cat_{pIP501}).

Table 23-25 Distribution of Antibiotic Resistances of Antibiotic-Resistant Enterococci Isolated from 56 Cheeses in 1980–81 (15 strains), in 1991 (12 strains), and 1995 (29 strains)

Antibiotic	*Number of Resistant Strains*
Gentamicin	45
Tetracyclin	33
Erythromycin	27
Chloramphenicol	18
Penicillin	10
Cefalotin	8
Fucidin	8
Furadoin	5
Rifampicin	4
Vancomycin	4

Note: All cheeses were purchased as raw milk cheeses from different parts and countries in central Europe.

Source: Reprinted with permission from M. Teuber, V. Perreten, and F. Wirsching, Antibiotikumresistente Bakterien: Eine Neue Dimension in der Lebensmittelmikrobiologie, *Lebensmittelwissenschaft und Technologie,* Vol. 29, pp. 182–198, © 1996, Frieden Verlag.

It should be mentioned that antibiotic-resistant enterococci were normally not detected in cheeses known to be made from pasteurized milk. However, if enterococci are detected in cheeses made from pasteurized milk, this is a matter of post-pasteurization contamination, or of high levels of enterococci ($>10^4$ cfu ml^{-1}) in milk before pasteurization (D-value around 2 minutes at 65°C, z-value up to 8°C), or of the use of starter cultures containing enterococci.

An interesting antibiotic-resistant *Lactococcus lactis* subsp. *lactis* strain was isolated from a raw milk Brie cheese (10^8 cfu g^{-1}). This strain was resistant to chloramphenicol, tetracycline, streptomycin, and norfloxacin. The resistance genes were localized on a 30 kilobase plasmid, which was completely sequenced.[106] This composite plasmid had 29 open reading frames: 15 ORFs including 6 IS elements had to do with DNA rearrangement, regulation, mobilization, and replication, 7 with antibiotic resistance, and 7 are still unknown, ill defined, or truncated. In this plasmid, *Lactococcus lactis* K214 has, with the help of IS elements, collected genetic information from four other species *(Listeria monocytogenes, Enterococcus faecalis* and *faecium, Staphylococcus aureus)* as evidenced by the high DNA homology of the sequenced genes with known genes from clinical isolates of such bacteria (Figure 23-11). The data so far collected demonstrate the presence of transmissible antibiotic-resistant genes in bacteria in raw milk cheeses (and in pasteurized cheeses if recontaminated!). The use of enterococci as starter cultures should be further questioned on the basis of the high gene-exchange potential of these bacteria irrespective of whether they are pathogenic or not. As a consequence, if we want to minimize the spread of antibiotic-resistant bacteria in the human population, food products containing antibiotic-resistant bacteria have to be banned generally from consumption, and specifically for high-risk parts of the population. In the case of cheeses, the use of pasteurized milk is an alternative to avoid such problems if recontamination of the treated milk after pasteurization is prevented.

23.8 CONCLUDING REMARKS

Modern fermented dairy products (sour milk, yogurt, and cheeses) have directly evolved from traditional, spontaneously fermented commodities that are part of the human cultural inheritance. The scientific exploration of the responsible microorganisms has resulted in a clear taxonomic differentia-

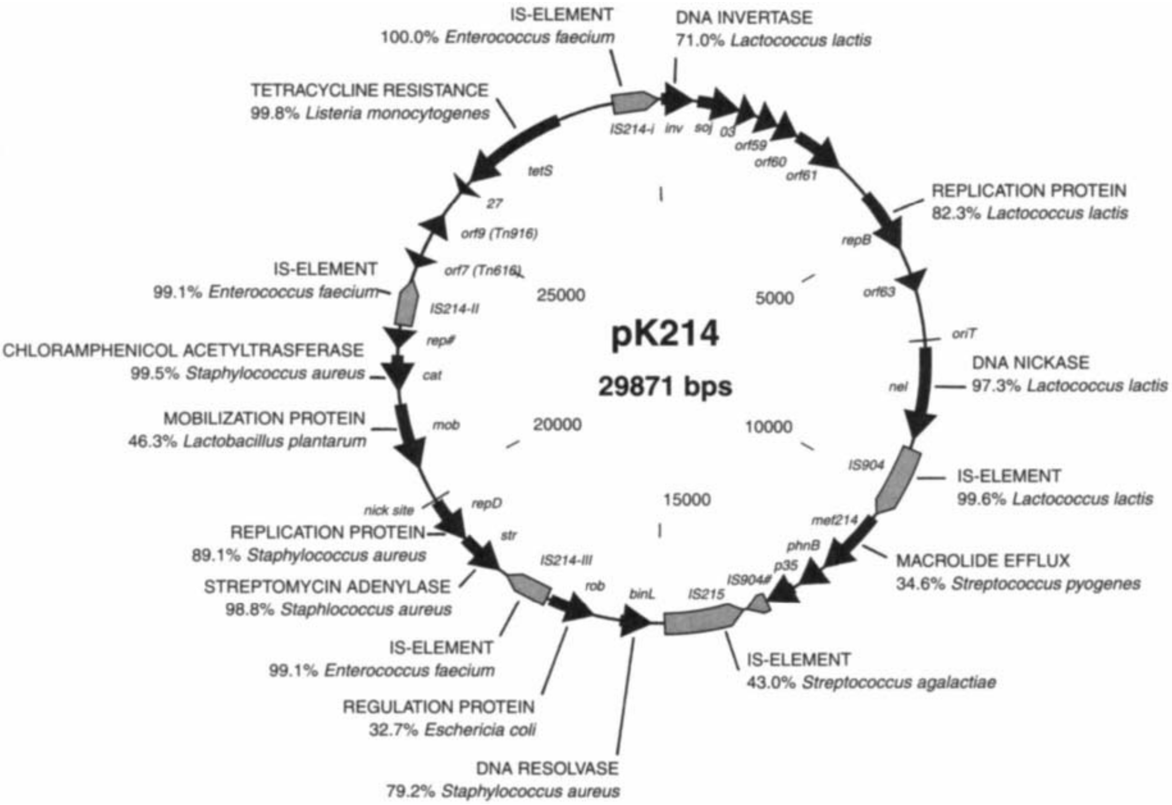

Figure 23-11 Molecular Structure of an Antibiotic-Resistant Plasmid from *Lactococcus lactis* subsp. *lactis.* The plasmid was detected in strain K214 isolated from a raw milk Brie. Its complete nucleotide sequence revealed that the resistance genes are almost identical with genes previously described in pathogenic bacteria like *Listeria monocytogenes* (tetracycline resistance) and *Staphylococcus aureus* (chloramphenicol and streptomycin resistance). The composite plasmid has obviously been assembled with the aid of insertion elements. The % data relate to amino acid identity of the corresponding proteins. *Source:* Data from V. Perreten, et al., Antibiotic Resistance Spread in Food, *Nature,* Vol. 389, pp. 801–802, © 1997.

tion of the technologically useful lactic acid bacteria, bifidobacteria, brevibacteria, propionibacteria, yeasts, and molds (*Penicillium camemberti* and *P. roqueforti*) from undesirable pathogenic and potentially pathogenic microbes like enterobacteria, staphylococci, listerias, *Brucella* spp., enterococci, and mycotoxin-producing fungi.

The biochemical reactions of starter cultures contributing to the typical properties of sour milk, yogurt, and cheeses are well characterized. Efficient and microbiologically safe starter culture preparations in liquid, freeze-dried, or deep-frozen, concentrated forms are provided in sufficient diversity by a responsible starter culture industry. One problem, however, not yet completely solved is the bacteriophage infection of lactic acid bacteria in cheese manufacture that cannot be performed with heat-sterilized milk. Whether genetically modified phage-resistant starter cultures developed by molecular biologists will be able to overcome the problem will depend on a complex set of issues including biosafety concerns, legal, and consumer acceptance.

The main hygiene issue is the use of raw milk for cheese making if the milk is contaminated with pathogenic bacteria that survive and eventually multiply during cheese making and ripening (*Salmonella, Brucella, Listeria monocytogenes, E. coli* O157, *Staphylococcus aureus,* and others). Likewise, recontamination of pasteurized or microfiltered milk and cheeses made from these substrates has been observed, but can be prevented by a proper hazard analysis critical control point (HACCP) system. A specifically high hygienic risk remains in raw milk soft cheese due to lack of hurdles (high a_w values and increased pH values during ripening). Recently, the presence of antibiotic-resistant pathogenic and potentially pathogenic bacteria (staphylococci and enterococci) in cheeses has been of increased concern.

The use of fermented dairy products as vehicles for probiotic bacteria (mainly certain lactobacilli and bifidobacteria) has gained economic importance. The claimed health effects for the normal healthy consumers remain to be established.

24 Eggs and Egg Products

Ronald G. Board

CHAPTER CONTENTS

24.1 Introduction
24.2 The formation, structure, and composition of eggs
24.3 Changes in the structure and composition of eggs with time
24.4 The antimicrobial defense systems in eggs
24.5 Microbial infection of eggs during passage through the oviduct
  24.5.1 The incidence and extent of microbial contamination of egg contents
  24.5.2 Infection in the oviduct
24.6 The microbiology of rotten eggs
24.7 Course of microbial infection of eggs
  24.7.1 Trans-shell infection
  24.7.2 The lag period
24.8 Egg products
  24.8.1 The innovative phase
  24.8.2 Pasteurization
  24.8.3 Value-added egg products
24.9 The future
References

24.1 INTRODUCTION

Most eggs for commerce are laid by the domestic fowl, *Gallus gallus*. Three facets of egg and egg product research will be discussed in this chapter.

1. The rotting of eggs in the distribution chain led to extensive investigations of the course of microbial infection of the contents of shell eggs. Not only were the major causative agents of rots identified but also several components of the antimicrobial defense systems in eggs.
2. A progressive increase in the number of shell eggs used to make egg products over the past 50 years has focused attention on the link between the microbiological status of eggs and the microbiological quality of egg products, especially with respect to foodborne pathogens, particularly *Salmonella.* This trend and the importance of this link is likely to be accentuated in the next few years. It has been forecast[8] that approximately 50% of eggs produced in the United States (US) will be used to prepare egg products by the end of the century.
3. The recent "pandemic" associated with *Salmonella enteriditis* has drawn attention to the contribution that an intensive and vertically integrated poultry industry can make to the dissemination of a particular foodborne pathogen among humans. Studies of this topic have identified the inadequacy of our knowledge of the antimicrobial systems present in the oviduct of hens as well as of the changes that occur in stored eggs.

There has been a tendency for topics 1 and 3 above to be studied in an intellectual vacuum because the role of the egg in the breeding biology of birds has been ignored. Birds produce cleidoic (closed box) eggs. A hen lays down a food store (principally in the yolk), a reservoir of water (mainly in the albumen), and a depot of minerals (in the shell). The first two must be sufficient in amount and chemical composition to support embryogenesis and to sustain a chick for a short period after hatching. The embryo exchanges O_2 and CO_2 with the atmosphere via pores in the shell. An egg represents a huge investment of time and effort on the part of a hen. Obviously, natural selection must have endowed an egg with a defense of this investment against colonization by saprophytic microorganisms. Studies of the rotting process (see below) led to the recognition of several antimicrobial systems and the realization that their efficiency waned with time, and that they were negated by inappropriate treatment of eggs at any stage from oviposition onwards. If one assumes that the domestic fowl lays a clutch of 12 to 14 eggs before settling down to incubation and that it will take about 5 days for the yolk (the most vulnerable entity) to be fully enveloped in a cellular rather than a nonliving (fibrous) membrane, then it can be assumed that the first egg of a clutch would need an integrated antimicrobial system for about 20 days with storage at ambient temperature. As will be noted repeatedly in this chapter, microbiological problems in eggs tend to be manifested some 20 days post-oviposition.

24.2 THE FORMATION, STRUCTURE, AND COMPOSITION OF EGGS

For a detailed discussion of this topic, see Burley and Vadehra.[32] The yolk (water, 47.5%; lipid, 33.0%; and protein, 17.4% by weight) of the egg is laid down in an ovarian follicle, the bulk of the material being deposited over a 6 to 10 day period (Figure 24-1). On leaving the follicle, the yolk is enveloped in a fibrous membrane. Additional fibrous material as well as ovomucin, lysozyme, and other proteins of relatively small molecular weights are laid down on this membrane when the yolk enters the oviduct. At maturity, the yolk (vitelline) membrane is trilaminate, two fibrous layers being separated by a continuous membrane the structure and chemical composition of which are unknown. The yolk is encapsulated in oviductal proteins (Table 24-1) to form the egg white in the 4 hours it takes to pass along the oviduct, a tube—one end of which opens into the peritoneum and the other into the cloaca. The white (water, 88%; proteins, 11%; and free carbohydrate, 0.5% by weight of whole white) is enveloped eventually in material that forms the anastomizing fibers of the inner and outer shell membranes. These coaxial fibers have a core rich in elastin-like protein surrounded by a mantle of glycoproteins. The principal water reserve is laid down—in a process known as plumping—during, and for a short period following, the deposition of the shell membranes and the cone layers of the shell.

The outer shell membrane provides the foundation for the shell, which is built up over a period of about 20 hours. Calcium carbonate, as calcite in a polycrystalline state, is the major component. The shell is permeated with fibrous material formed from short peptides of hepatic origin. Pores (upwards of 17, 000 per shell), originate at the inner surface of the shell and terminate in a campanulate orifice at the outer (Figure 24-2). The cuticle, a relatively dense material rich in glycoproteins, is laid down on the surface of the shell. With a perfectly formed egg, the entire surface of the shell is covered with this material. At the time of lay the cuticle is a slippery, lustrous layer that dries rapidly on exposure to the atmosphere. Within a few minutes of laying, it dries out such that the shell is covered with a somewhat flakey, fissured layer and the outer orifice of a pore canal is crudely plugged with vesicular material.[24]

At oviposition, the avian egg has the gross structure depicted in Figure 24-3. At this time the yolk, which has a density greater than that of the white, is

Table 24-1 The Biological Properties of the Oviductal Proteins Present in the Albumen of the Eggs of Domestic Hens

Protein	*% of Albumen*	*Biological Properties*
Avidin	0.05	Avid binding of biotin
Riboflavin binding protein	0.8	Possible that riboflavin is bound such that microorganisms are denied this vitamin
Ovotransferrin	12–13	Avid chelation of Fe^{3+} dissociation constant ($\bar{K}_D$~10^{-29}M)
Cystatin	0.05	Inhibits thiol proteases ficin and papain (possible antiviral role also)
Ovomucoid	11.0	Inhibits trypsin
Ovoinhibitor	0.1–1.5	Binds trypsin, chymotrypsin, and several types of bacterial and fungal proteases
Ovalbumin	54.0	Structure indentifies it with serine-protease inhibitors but biological activity yet to be determined
Ovomacroglobulin	0.5	Serine protease inhibitory activity
Ovomucin	1.5–3.5	Endows albumin with high viscosity—this attribute enhanced through complex formation with lysozyme (inhibits viral hemagglutination)
Lysozyme	3.5	A 1, 4-ß-N-acetylmuramidase that cleaves the glycosidic bond between the Cl of N-acetyl muramic acid and the C4 of N-acetyl-glucosamine in bacterial peptidoglycans; contributes to integrity of albuminous sac through electrostatic interaction with ovomucin
Ovoglobulin G2	4.0	?
Ovoglobulin G3	4.0	?
Ovoglycoprotein	0.5–1.0	?

at the center of the egg, a situation that is mainly due to physical properties of the inner and outer thick albumen. The former envelopes the yolk and at opposing poles it is twisted into rope-like structures, the chalazae, that merge with the outer thick white. The slightly elastic chalazae allow limited rotation but impede lateral displacement of the yolk. The two thick albumens differ from the inner and outer thin white in having a higher content of ovomucin. This glycoprotein occurs in two forms, α-ovomucin and the insoluble (fibrous) ß-ovomucin.[104] The latter has the higher content of carbohydrate residues. An interaction between lysozyme and ovomucin probably contributes also to the fibrous nature of the thick albumen.

24.3 CHANGES IN THE STRUCTURE AND COMPOSITION OF EGGS WITH TIME

Figure 24-4 summarizes the gross changes occurring in the egg of the domestic hen from oviposition onwards. Many factors, including breed,[31,132] health,[76,122] age of bird, and especially storage temperatures,[93,108] influence the rate of change. The following features need to be stressed:

- Changes in the relative densities of the yolk and white, such that the tendency of the former to sink in the white of a newly laid egg is reversed in storage. This results from the diffusive loss of water from the albumen via the pores in the eggshell and the movement of water from the albumen (freezing point –0.42°C) to the yolk (–0.57°C) due to osmotic forces (difference in osmotic pressure, approximately 1.8 atmospheres). The progressive stretching of the vitelline membrane leads to a loss of elasticity and strength.[32]
- Breakdown of the ovomucin-lysozyme complex in the thick albumen[104] results in the yolk floating upwards until contact is made with the inner shell membrane. If an egg is stored broad

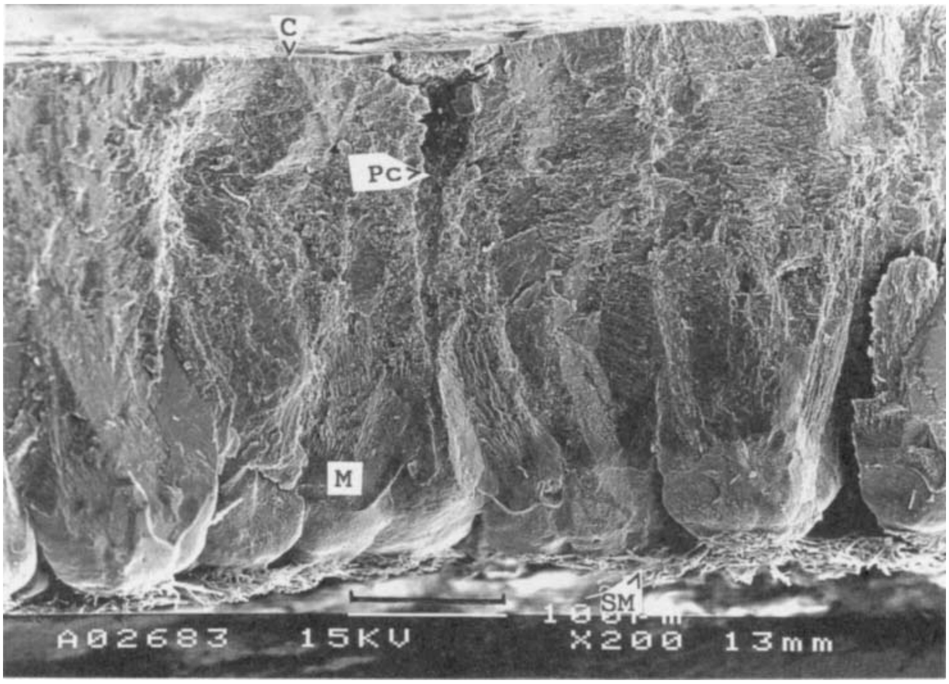

Figure 24-2 Radial Section of the Shell of a Hen Egg. PC, pore canal; C, cuticle; M, mammillary layer; and SM, shell membrane.

pole upwards, as is the case with the majority of eggs in commerce, the upward movement of the yolk will be arrested by the inner membrane of the air cell (Figure 24-4). This membrane moves progressively toward the center of an egg as the volume of the air cell increases to accommodate diffusive water loss.

24.4 THE ANTIMICROBIAL DEFENSE SYSTEMS IN EGGS

The antimicrobial defense systems of the hen's egg are listed in Table 24-2. The contributions of the first three components are well known. There is no direct evidence to implicate the fine structure of the yolk in the antimicrobial defense of an egg. The available evidence suggests that the yolk is devoid of any worthwhile defense apart from antibodies against organisms that have infected the hen.[106] Several workers, including Ayres and Taylor,[7] have demonstrated the rapid growth of bacteria inoculated into whole yolks with incubation at optimal temperatures for the test organism.[27] The mere act of inoculation may damage yolk structure such that bacterial growth is promoted. Burley and Vadehra[32] discussed three attributes of the yolk that could well have a bearing on this issue.

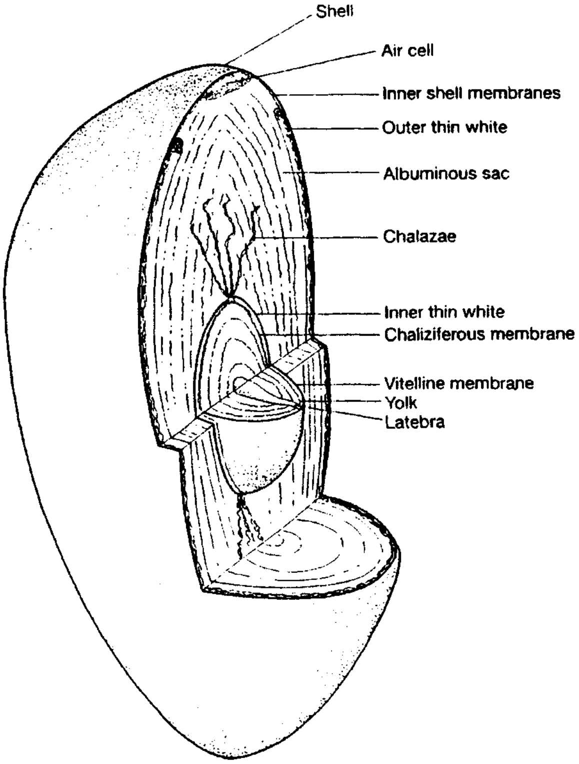

Figure 24-3 An Artist's Impression of the Hen Egg as Shown by Cut-away Sections. *Source:* Copyright © 1994, R.G. Board and R. Fuller.

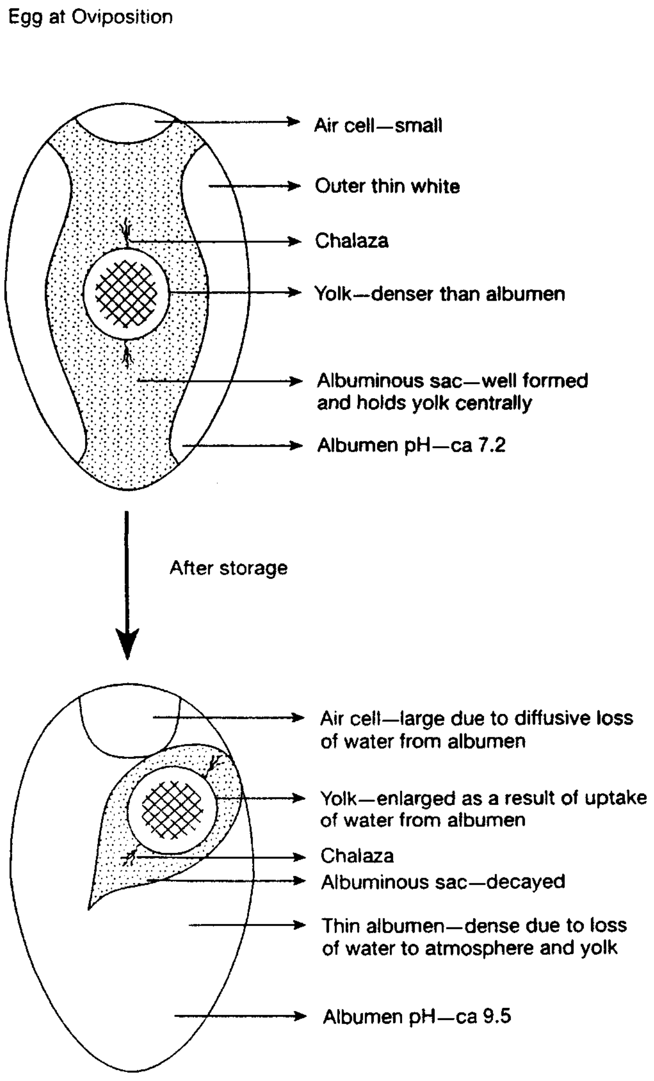

Egg at Oviposition
Air cell—small
Outer thin white
Chalaza
Yolk—denser than albumen
Albuminous sac—well formed and holds yolk centrally
Albumen pH—ca 7.2
After storage
Air cell—large due to diffusive loss of water from albumen
Yolk—enlarged as a result of uptake of water from albumen
Chalaza
Albuminous sac—decayed
Thin albumen—dense due to loss of water to atmosphere and yolk
Albumen pH—ca 9.5

Figure 24-4 A Summary of Changes Occurring in Eggs during Storage (reproduced with permission[21]). Many factors contribute to the changes occurring during storage *viz.* temperature, humidity of store, breed of hen, stage in laying cycle, health of hens, etc. Temperature is of paramount importance; slowest rate of change occurs in chilled eggs (*ca.* 4°C). *Source:* Copyright © 1994, R.G. Board and R. Fuller.

---

1. The yolk consists of concentric layers of light and dark material. These do not fuse with time. Burley and Vadehra[32] concluded therefore that the yolk has an inherent stability that could well hinder diffusion of material between yolk and white.
2. Partitioning of the yolk with trilaminar membranes has been observed in fixed material examined with transmission electron microscopy. Such partitions are not present in yolk extruded through a hole in the vitelline membrane. Burley and Vadehra surmised that such partitioning impeded diffusion of material in the yolk.
3. Dolman and Board (unpublished) demonstrated a negligible increase in the glucose and amino acid contents of the albumen of eggs stored at 25°C for 42 days. There is also a marked and persistent asymmetry in the pH of the egg's contents.[105] At the time of lay the pH of the white is about 7.6 and that of the yolk 6.0. Within a short period of storage, the pH of the albumen rises to >9.5 as CO_2 is lost, whereas the yolk is still slightly acid after 100 days at 2°C.

All of the above need to be considered in any discussion of the integrated working of the antimicrobial defenses of eggs (Figure 24-4).

24.5 MICROBIAL INFECTION OF EGGS DURING PASSAGE THROUGH THE OVIDUCT

24.5.1 The Incidence and Extent of Microbial Contamination of Egg Contents

These have been contentious issues since a pioneering study in 1873. In that year Gayon,[56] with the support of Pasteur, refuted the claims of the protagonists of spontaneous generation, namely that vigorous shaking induced putrefaction of an egg. From a review of studies done over the next 50 years or so, Romanoff and Romanoff[105] noted that incidences of contamination of 3% to 87% of egg contents had been reported and that upwards of 40 "species" of bacteria had been isolated. They surmised, "it is quite likely that these figures were obtained because of the technical difficulties encountered in working with material of such unusual consistency and physical structure." Haines[61] was of the same opinion, "It may be stated categorically that it is impossible to make a completely satisfactory bacteriological analysis of an egg." These opinions are still valid, even allowing for the introduction of safety cabinets and improved aseptic techniques. Moreover, the identification of a possible infection site in the white is largely guesswork. Neither of these issues is of importance in the case of rotten eggs because the evidence supports but one conclusion, rot-producing microbes infect eggs post-oviposition (Figure 24-1). They are of importance with pathogens that cause vertical infection in poultry flocks or those that are passed via the egg contents to humans. Barrow[13] stressed that a number of virulence factors are re-

Table 24-2 The Antimicrobial Defense Systems of the Hen Egg

Component	Mode of Action
Biological structure	The compartmentalization of an egg's contents (Figure 24-3) ensures that at oviposition and for a short period thereafter the yolk—the most vulnerable entity in terms of microbial breakdown—is located at the greatest distance from microorganisms that infect the albumen via the trans-shell route
The cuticle, shell, and shell membranes	A physical barrier to trans-shell infection of the albumen (see Figure 24-2)
The white	**Physical** The gelatinous/fibrous nature of the white (a) impedes bacterial movement, and (b) acts as a shock absorber such that the vitelline membrane and the organization of the yolk are protected form physical damage
	Chemical The albumen is an inadequate medium for microbial growth because of the alkalinity (pH 9.6), its low content of simple nitrogenous compounds, and the presence of oviductal proteins having a range of biological properties (see Table 24-1)
The vitelline membrane	A physical barrier that impedes the ingress of microorganisms to the yolk
The yolk	Fine structure is the most likely impediment to the diffusion of small molecules into the surrounding albumen

quired for the survival of a microorganism in the hen's alimentary tract and its bloodborne passage to, and persistence in, the reproductive tract, with contamination of the egg contents as a possible sequel. The virulent, host-adapted avian pathogens, *Salmonella gallinarum* and *S. gallinarum-pullorum,* pass from hen to progeny by this route. With the latter, egg infection occurs most commonly after the egg has been released from the ovary. Barrow contends that the majority of eggs will be infected in the vitelline membrane or albumen. Ova in follicles may be infected but, if such were included in an egg, embryogenesis would be unlikely to take place and hence vertical transmission would not occur. The recent "pandemic" in humans associated with *Salmonella enteritidis*[5] has revealed that a non–host-adapted serotype of this genus, but one with virulence determinants that aid carriage by a systemic infection of domestic fowls,[54,58,73] does mimic *S. gallinarum-pullorum* in that it enters the oviduct, possibly via the vascular system in many cases, and infects the contents of the egg. The oviduct can become infected with salmonellas that move up from the cloaca. The available evidence suggests that, with some eggs infected with *S. enteritidis* by either route, embryogenesis proceeds normally and a healthy (even if infected) neonate is produced.

Methods of poultry husbandry can influence infection of the oviduct and the incidence, and perhaps the periodicity also, of egg contamination with salmonellas. Thus, Reiber et al.[103] isolated salmonellas from semen taken from cockbirds and there is evidence[101,102] that semen may serve as a vehicle for transmission of salmonellas to the hen, which may result in sporadic production of contaminated eggs. The incidence of salmonella in the crops[63] of laying hens increased significantly when hens were starved for 24 hours.[72] Hens nearing the end of their laying cycle are sometimes deliberately stressed (by starvation, no access to water, or reduction in lighting) in order to induce a molt, because egg production returns to a commercially acceptable level following a molt. Starvation has been associated with an increased incidence of both systemic infection in, and fecal shedding of, salmonellas by laying hens.[67–69] In an outbreak of salmonellosis among the customers of a restaurant, eggs containing *S. enteritidis* were implicated and their source identified.[120] It is of interest to note two features of the implicated production farm:

1. Some hens were shown to be carriers of *S. enteritidis* a few weeks before the outbreak.
2. A few weeks before the outbreak strife between management and labor caused the hens to be deprived of water and food for 2 to 3 days.

In view of these examples of the probable influence of stress on the interaction between the hen and salmonellas, it is tempting to speculate that the caged hens studied by Humphrey and his collaborators[74] may have been unwittingly stressed on some occasions. This could have been the reason for the observation that the incidence of infected eggs tended to be clustered in just a few days of what was a protracted study that sought to establish the incidence of salmonella contamination in eggs laid by naturally infected hens.

The results obtained from surveys with this overall objective must be considered in the context of (1) the history and management of the flock(s) producing the eggs included in a survey, and (2) the bacteriological methods used in a survey. It is evident from the above discussion that stress is likely to lead to a sporadic increase in the incidence of egg contamination above background levels. As enrichment culture is essential in order to increase the number of salmonellas in freshly laid eggs to levels that can be detected and isolated by direct plating, the choice of sample size of white or whole egg contents and enrichment methods will be important in the case of (2) above. This was exemplified in a recent study[53] of pooled egg contents spiked with *S. enteritidis* 13a. Thus, direct plating on brilliant green agar from a pooled sample immediately after spiking required an inoculum 10^4-fold larger than in a sample that had been incubated with an enrichment medium for 24 hours before plating. Moreover, supplementing samples of the pooled contents of 10 eggs with Fe increased significantly ($P<0.005$) the percentage of pools (inoculum size, fewer than 10 salmonella per pool) that were demonstrated by direct plating to be infected.[55]

As noted above, it is difficult to sample viscous albumen aseptically; thus, caution must be exercised when assessing the results of surveys that sought to establish the incidence of *Salmonella* contamination of egg contents. In a review of data obtained from an investigation of the contents of 8,698 eggs obtained from 22 flocks (commercial layers both battery and free range, layer and broiler breeds, and experimental), Humphrey[71] recorded a range in the incidence of contamination with *S. enteriditis* of from 0.1% to 1.0% (average, 0.6%) of eggs. He noted that only a few salmonella occurred per egg and deduced that the outside of the vitelline membrane or the albumen surrounding it were the principal sites of contamination.

From a review of the literature on *Salmonella* infection of eggs,[45] it was noted not surprisingly that widely differing frequencies of internal infection in eggs have been reported *viz.* 5 out of 10 eggs from a small domestic flock, 10 of 613 eggs from a deliberately infected flock of 42 hens, and 11 of 1,119 eggs from two naturally infected flocks of 23 and 15 birds. Some infected eggs contained less than 10 *S. enteriditis* PT4 per egg. Vugia et al.,[143] who investigated an outbreak of salmonellosis among customers of a chain of restaurants, deduced that 1 in 12 of the eggs from the farm supplying the restaurant may have been infected with *S. enteriditis* at the time of the outbreak. In summary, the available evidence reveals that eggs are infected in the oviduct with *S. enteriditis.* It does not allow, however, conclusions about the incidence or the precise site of infection in eggs.

24.5.2 Infection in the Oviduct

As one end of the oviduct is located in the cloaca, there is at least a theoretical possibility of microorganisms migrating up the lumen of this organ. This possibility was examined by several workers in the early years of the 20th century. From a review of their observations, it was concluded[61] "that the healthy avian oviduct approximates to sterility and has, in fact, mechanisms tending to rid it of occasional invading microorganisms." Phagocytosis, mechanical action of the oviduct, which tends to force contents of the lumen toward the cloaca, and the bactericidal action of unidentified secretions have been cited[29] as possible agencies involved in the removal of causal contaminants from the oviduct. The possible susceptibility of the oviduct to ascending infection has been largely ignored since the review by Haines.[61] As noted by Bruce and Drysdale,[29] the few studies that have been done dealt with very few birds. They collected 656 fertile eggs over a 10-day period from 140 individually caged birds (broiler breeders) that were coming to the end of their laying cycle. The eggs were incubated, and the incidence and type of contamination of eggs that failed to hatch assessed; fewer than 4% of such eggs were contaminated. The hens were slaughtered, both ends of the oviduct were clamped before removal from the carcass. The lumen of the oviduct was rinsed with 10 ml of Ringers solution, and the number and types of bacteria in this suspension determined. Sixty-three percent of the oviducts were contaminated, the level of contamination ranging from $\leq 10^3$ to $>10^6$ organisms/oviduct. The following organisms were isolated: *Micrococcus* spp., *Bacillus* spp., *Lactobacillus* spp., *Escherichia coli,* nonfermentative Gram-negative rods, and nonsporing Gram-positive rods. A different range of organisms was isolated from eggs that failed to hatch. A similarly diverse range of organisms was recorded by Harry[64] who studied the contamination of the oviduct and ovaries of hens. It is notable that the diversity recorded by these workers matched that of earlier ones (reviewed by Romanoff and Romanoff[105]) who characterized the contaminants of egg contents. Indeed such diversity poses important questions. Is it possible to adopt appropriate and rigorous aseptic procedures such that there can be absolute certainty that isolates from egg contents or the lumen of an oviduct were truly indigenous to the sample being examined? If this question is answered in the affirmative, then another question must be posed. Are the chances of contamination of eggs in the oviduct so high that oviductal proteins have been selected during evolution to protect the yolk from chance contamination in the oviduct as well as from colonization by saprophytic microorganisms post-oviposition? This topic is discussed further in Section 24.7.

24.6 THE MICROBIOLOGY OF ROTTEN EGGS

The microbiology of rotten eggs attracted a great deal of attention in the first half of the 20th century. The reason for such interest was noted by Maurer, "He who has seen the wagon loads of rotten eggs hauled from the establishments of our big egg dealers fully appreciates the tremendous waste connected with the industry."[86] When Maurer made this observation about conditions in the US, egg production was on a small scale and little attention was given to the need to collect eggs regularly, clutches of eggs were taken occasionally from the nests of hens that chose to lay away from the poultry house and, in the absence of controlled lighting, eggs produced during the spring/summer flush were stored for long periods. Such conditions still prevail in some parts of the world. With storage, diffusive water loss from eggs results in weight loss and a reduction in value. Consequently, particular attention was directed at the selection of a humidity that minimized weight loss and mold growth. Fragile white growth of mold on the shell surface was sometimes taken as evidence that the humidity of the store was being maintained at a satisfactory level.[115] If, however, the relative humidity was maintained at 96% to 100% for three months at chill temperature, then dark mold growth developed on the shell and the egg contents became infected with hyphae that had penetrated the pore canals. Species of *Penicillium, Sporotrichum, Thamnidium, Mucor,* and *Alternaria* were isolated from eggs stored under very humid conditions.[61,144] Sharp and Stewart[115] suggested that failure of molds to grow at relative humidities less than 94% may have been associated with "a restriction of the food supply as controlled by moisture." Two strains of protease-producing (cuticle-digesting) pseudomonads were isolated from the surface of shells of eggs stored in very humid conditions.[23] Yeasts also grew on the shell surface, but their growth appeared to be dependent upon nutrients released from the cuticle by the pseudomonads. High incidences of mold growth and spoilage of eggs are, of course, a thing of the past in developed countries with their intensive poultry industry. It may well not be so in countries in which small egg producers are still major suppliers to unsophisticated markets. Even so, the occasional rotten egg does reach the consumer in developed countries, and the consumer's reaction to the smell and appearance of a rot may well influence future purchases.

Gram-negative bacteria are the dominant cause of rots in stored eggs.[30] In studies conducted between 1938–1947 on addled eggs derived from three states in Australia,[1] a total of 3,873 rotten eggs were examined. Of these 1,475 were identified as green rots (causative organism, *Pseudomonas fluorescens*), 1,079 as colorless rots (*Pseudomonas, "Achromobacter"* spp.), 1,142 as black rots (mainly *Proteus* spp. but occasionally *Pseudomonas* spp.), and 121 as pink rots (strains of *Pseudomonas*). This study revealed also the importance of storage temperature and farm. No rots were evident, as demonstrated by candling, in eggs stored for 6 to 8 weeks at 0° to 0.6°C (the temperature of the storage compartment on ships used to transport eggs from Australia to the United Kingdom [UK] at that time). With subsequent storage at ambient temperature for 24 to 26 days, 19.1% (range 1–65%) of the eggs developed rots. A high incidence of rots was associated with eggs coming from farms that machine-cleaned eggs.

An extensive study was done in 1950 of rots in eggs obtained from farms and packing stations in British Columbia, Canada.[136–138] With 16,652 eggs taken directly from farms and stored for 6 to 7 weeks at 16°C, an overall spoilage rate of 3.19% was found. None of the eggs from some farms spoiled, whereas a 26% spoilage rate was noted with those from one farm. An insignificant incidence (0.42%) of spoilage occurred in clean eggs collected from nest boxes containing clean litter or from the wire floor of "roll away" nests (a system common in battery cages). The well-being of eggs was unaffected by storage in dirty egg boxes. The incidence of rots in heavily soiled eggs from various farms ranged from 0.6% to 11.00% (average, 2.73%). The highest incidence of rots was found in eggs washed on the farm, varying from 0% to 19.8% (average, 7.44%) in one survey and from 0% to 22.6% (average, 6.06%) in another. Two hundred twenty-eight bacteria were isolated from 81 rots that developed in 591 eggs during 6 weeks storage at 25°C. Although these isolates were characterized in some detail,[50] the identity of species and, in one instance genus (for example, *Aeromonas* identified with *Proteus*), would now be considered dubious simply because of the inadequate identification schemes then available; even so, members of all the genera of bacteria that Haines[60] and Alford et al.[1] had associated with the addling of eggs were isolated.

These same genera were represented in the 345 bacteria isolated some 20 years later[17] from eggs that had rotted on the farm or under controlled conditions in the laboratory in the UK (Table 24-3). The main features of rots produced by particular bacteria and physiological attributes associated with such changes are given in Table 24-4. Microorganisms lacking all these attributes (eg, *S. enteriditis, Alcaligenes faecalis*) form large populations in eggs infected naturally or deliberately but cause only slight turbidity in the albumen. Eggs infected with these organisms would not be detected in routine candling nor by a cursory examination when broken out in a container that prevented light transmission through the albumen. This situation may have resulted in the use of eggs heavily contaminated with salmonella in the kitchen of the home or canteen, or inclusion in products in egg-breaking plants. Eggs containing large numbers of *"Achromobacters"* have been found among those awaiting processing in such a plant.[77]

It is common for addled eggs to contain two or more species of bacteria. If eggs are inoculated with pure cultures of these isolates, in general only one produces the changes noted in the original. The vast majority of spoilage bacteria are commonly present in soil, in water, in the deep litter on the floor of poultry houses, in decaying feces of hens, and on hay and straw used to line nest boxes.[65] Thus, infection of eggs after laying is of infinitely greater importance than oviductal infection. The genera of bacteria listed in Table 24-3 have been associated with the addling of eggs produced in Australia, South Africa, Canada, and the UK. There appears to have been no change in their incidence over a 30-year period. Thus, properties of eggs, rather than climatic conditions or farming practices, select rot-producing bacteria from what may well be a very heterogenous, initial infection. Gram-positive bacteria, commonly present in the oviduct,[29] are very rare contaminants of eggs that have rotted during storage at ambient or chill temperatures. These bacteria can be important contaminants of the contents of hen eggs incubated at 37° to 39°C. Seviour et al.[113] examined 1,160 "incubator clears," ie, eggs in which germinal development had not occurred and which were not opaque to transmitted light when candled. Twenty-five percent of the eggs contained large numbers of bacteria. When broken out, 13% of these eggs had cloudy whites and most of these had custard-like material on the surface of the yolk. Of the 350 bacteria isolated in pure cul-

Table 24-3 The Identity of Bacteria Isolated from Rotten Eggs[a]

Identity	*Occurrence in Eggs*	*Type of Rot Produced in Inoculated Eggs*[b]
Pseudomonas		
fluorescens	Common	Pink rot
putida	Common	Fluorescent green rot
aeruginosa	Uncommon	Fluorescent blue rot
Stenotrophomonas maltophilia	Uncommon	Green rot
Alcaligenes faecalis	Common	No change
Flavobacterium spp.	Very uncommon	Yellow pigment in shell membrane
Cytophaga spp.	Very uncommon	Yellow pigment in shell membrane
Aeromonas liquefaciens	Uncommon	Black rot type 1
Proteus vulgaris	Common	Black rot type 2
Cloaca spp.	Common	Custard rot or no change
Serratia marcescens[c]	Uncommon	Red rot
Citrobacter spp.	Common	No change
Bacillus, Arthrobacter, Micrococcus, and *Streptococcus* species isolated occasionally.		

[a] Based on a study of 345 isolates from eggs that had rotted at the poultry farms or under controlled conditions in the laboratory.

[b] Description of rots based on Haines[61] and Florian and Trussell.[50] See Table 24-4 for additional details.

[c] An uncommon rot in hen eggs described by Zagaevsky and Lutikova[146] and in duck eggs by Panda and Rao.[99]

Table 24-4 Characteristic Features of Rots Produced in Hen Eggs by Bacteria and Key Attributes of Causative Organisms

Rot (causative organism)	*Changes in Egg*	*Pig.*[a]	*Prot.*[b]	*Lec.*[c]	*H_2S*
Pink rot *(Pseudomonas fluorescens)*	Mealy yolk; fluorescent green albumen	+	+	+	–
Fluorescent green rot *(Pseudomonas putida)*	Fluorescent green albumen	+	–	–	–
Fluorescent blue rot *(Pseudomonas aeruginosa)*	Fluorescent blue albumen	+	+	+	–
(Stenotrophomonas maltophilia)	Gelatinous, amber-like yolk striped with olive green pigment, strong almond smell	–	+	–	+
Black rot, type 1 *(Aeromonas liquefaciens)*	Gray, watery albumen; gelatinous yolk; blackened throughout	–	+	+	+
Black rot, type 2 *(Proteus vulgaris)*	Dark brown albumen; dark brown, mealy yolk	–	+	–	+
Custard rot *(Cloaca* spp.)	Yolk encrusted with custard-like material	–	–	+	–

[b] Prot., proteolysis.
[c] Lec., lecithinase production.

ture, 74 were identified with *Staphylococcus,* 205 with *Micrococcus,* and 36 with coliforms (25 as *Escherichia coli).* The origin of these contaminants is unknown, but the production of eggs in a dusty atmosphere may have led to contamination of the shell membranes. Formaldehyde fumigation of the eggs may have played a part also. *Streptococcus* spp., *Micrococcus* spp., and Enterobacteriaceae were the principal contaminants found in heavily infected eggs among 2,542 incubator rejects.[113] A study of 95 addled eggs of domestic ducks obtained from 2 commercial hatcheries and >1,400 addled eggs of about 50 species of waterfowl from the hatcheries of the Wildfowl Trust, Slimbridge, Glos, UK, resulted in the isolation of 317 pure cultures.[113] Sixty-four percent of these were identified with *E. coli,* 8.5% with *Staphylococcus,* and 15% with *Micrococcus* spp. All of the *E. coli* isolates from waterfowl eggs formed large mucoidal colonies (individual cells encapsulated) when grown on media containing glucose or lactose. None of the *E. coli* from hen eggs did so. *Escherichia coli* was an important cause of colorless rot in duck eggs obtained from various markets in Mysore.[99] Differences in the biological properties of the oviductal proteins of ducks and hens, rather than differences in husbandry practices, may be responsible for the selection of such different microbial associations in the eggs of the two groups of birds. The poor public health record of duck eggs in the context of salmonellosis in humans[110] may be linked to the selection of "smooth" rather than "rough" strains of Enterobacteriaceae by the duck egg white rather than the "porosity" of the shell, a commonly cited reason.[145]

24.7 COURSE OF MICROBIAL INFECTION OF EGGS

There are three possible routes for the initial infection of an egg's contents (Figure 24-1). (1) **Transovarian infection**—the yolk within the follicle of an ovary is infected with bloodborne microorganisms. This route is of particular importance in hens infected with host-specific pathogens.[13] It will not be discussed further because it appears unimportant in the context of table eggs or egg products. (2) **Oviductal infection**—the vitelline membrane or egg white is infected during transit along the oviduct. Microorganisms are introduced into the lumen of this organ via (a) the vascular system, (b) upward migration from the cloaca,[5] or (c) husbandry practices such as artificial insemination.[103] Contamination of the oviduct is accentuated in stressed hens.[67] (3) **Trans-shell infection**—microorganisms on the surface of the shell are translocated to the underlying shell membrane.[18] This may be an active process. If eggs are stored in very humid conditions, molds grow on the shell surface and hyphae penetrate the pores in the shell. Infection passes inwards from the shell membranes until eventually the entire white and yolk are colonized.[23] This means of infection is extremely uncommon in eggs produced by intensively managed hens and sold through controlled marketing channels. Bacteria have a passive role in trans-shell infection under normal commercial conditions. Practices such as egg washing may cause the translocation of bacteria from the outside of the shell to the underlying shell membranes.[29]

There is a common sequence of events in the progression from the initial (light and localized) to the systemic and heavy infection of the entire contents of eggs infected by the oviductal or trans-shell route. There is a lag period of very variable duration followed by a short phase of rapid bacterial multiplication. Subsequently, the white or, more commonly, both the yolk and white will become grossly changed in appearance (Table 24-4).

The progression to a generalized infection of an egg's contents can be interpreted when the course of infection is considered in the context of the workings of a complex antimicrobial defense system.

24.7.1 Trans-Shell Infection

The cuticle-pore complex, shell, and shell membranes (Figure 24-2) are potential barriers to trans-shell infection of egg contents.[18,90] Romanoff and Romanoff[105] were probably the first investigators to identify the cuticle's contribution to the egg's defense. Sparks and Board[124] demonstrated that the barrier properties of a mature cuticle are much greater than those of an immature one. Thus, there was 100% infection of the contents of eggs placed on fresh hen feces when the cuticle on the shell was wet and lustrous but only a 16% infection rate when it had dried out. Infection of the contents occurred in all 18 freshly laid eggs sprayed with *Salmonella typhimurium*.[95] When freshly laid eggs were partially submerged in relatively dry nest litter contaminated deliberately with this organism, the contents of 10 out of 17 eggs were contaminated.[95] The incidence of contamination of eggs of both layer and broiler strains of hens laid in the litter on the floor of the poultry house was invariably higher than of those laid in nest boxes.[119] These observations indicate that contamination of egg contents is highly probable if an egg is laid in a contaminated environment. This situation is recognized by the management of poultry breeding farms. Egg collection and nest hygiene have been identified as two of the "key critical control points" in an integrated system of *Salmonella* control of hatching eggs. The following procedures are commonly in place: (1) collection of eggs from nests four times per day, (2) cleaning of nests and sanitizing, eg, with formaldehyde prills once every 14 days, and (3) monitoring standards of egg hygiene by laboratory tests on a monthly basis.

Until recently there was a concensus view that penetration of contaminated water into the pore canal (Figure 24-2) was an essential step in trans-shell infection of eggs having mature cuticles.[62] Penetration rarely if ever occurs simply through contact of a shell with water. The microstructure of the surface of the cuticle, especially that adjacent to the shell in the outer pore orifice, is such that the contact angle (Θ) required for capillary attraction of water rarely occurs. It does so on occasions in eggs from which the cuticle has been removed with EDTA.[123] Work is generally needed to force water into the pore canal. This can be done in three ways.[22]

1. When a warm egg is immersed in cold water, water is pulled into the pore canals as a result of a partial (negative) pressure generated by the reduction in volume of the yolk and white being greater than that of the space enclosed by the shell.
2. Eggs immersed in water are exposed to a pressure less than atmospheric, and then normal pressure is suddenly reimposed.
3. Eggs immersed in water are subjected to a pressure greater than atmospheric.

The shell of the hen's egg contains $1.0 - 1.7 \times 10^3$ pores. Porosity was a nebulous term until the work of Ar et al.[6] They defined porosity thus:

$$G_{H_2O} = \dot{M}_{H_2O} / \Delta P_{H_2O}$$

where G_{H_2O} = water conductance expressed as mg of water loss per mm Hg of difference in water vapor pressure across the shell per day

$\dot{M}_{H_2O}$ = water loss from the egg (mg d^{-1})

ΔP_{H_2O} = difference in water vapor pressure across the egg shell (mm Hg)

G_{H_2O} is a measure of the number and size of the pores. It is constant once shell formation is complete.

No correlation was found[123] between the weight of water taken up by a warm egg (37°C) immersed in iced water and the porosity of its shell as measured by G_{H_2O} or the number of pores per shell ($r = 0.03$; P 0.05; $n = 70$). The amount of water taken up by eggs with shells from which the cuticle had been removed with EDTA was more than that of the control eggs but again there was no correlation between water uptake by, and water vapor conductance of, a cuticleless egg. No correlation was evident when the amount of water taken up by an egg was regressed against the amount of cuticle (dry weight) cm^{-2} of shell ($r = 0.50$; $P<0.05$; $n = 48$). Fissures resembling cracks in dried mud are a feature of the outer surface of the cuticle (Figure 24-2), especially that covering the outer orifice of a pore. Sparks and Board[123] measured the length, but not the width, of the fissures in the cuticles of groups of five eggs selected from those that had been shown to take up high, intermediate, or low amounts of water. Fissure length regressed against water uptake gave a good correlation ($r = 0.9$; $P<0.05$). No such correlation was evident when fissure length and water uptake for every one of 24 eggs were analyzed. The length and extent of branching of fissures in the cuticles of eggs cooled rapidly (forced convection with an air speed of 30.5 M min^{-1} and a temperature of 0°C) was greater than on eggs cooled by ambient storage.[49] One hundred percent of the first group of eggs but only 48% of the second were infected by the trans-shell route with *S. enteritidis*. In practice, there is only a very small weight change when a warm egg is immersed in iced water; 3–415 mg for normal eggs and approximately 350–610 mg for cuticleless ones.[22,123] The addition of a surfactant, Triton X-100, to iced water increased the weight gain of eggs.[123]

The shell membranes behave as semi-permeable membranes when they separate a fluid of high from one of low molarity. There is unhindered water uptake when a shell-less egg or one from which a small piece of shell has been removed is immersed in water. The wall of a well-formed pore canal (Figure 24-2) obviously imposes a drag sufficient to negate osmotic forces operating across the shell membranes in eggs. Work is therefore needed to flood a normal pore canal and to ensure also that water reaches the underlying membranes; the magnitude of the drag is not apparently changed by repeated flooding of the pore canal. Mean weight gains of 72.0 ± 13.0 (SD) mg of eggs ($n = 60$) subjected to method 3 above on one occasion and 130.0 ± 21.0 mg ($n = 60$) on two occasions have been reported.[96]

Various methods, including the addition of a pigment (eg, blue lake[77]), carbon black, and/or microorganisms to the slush ice,[22] have shown that flooding of the pore canals results also in particles being lodged in the underlying shell membranes. The number of pores flooded when eggs are immersed in slush ice varies. When a green pigment and carbon black were added to slush ice used to chill 97 white eggs, 48% had 0 to 19 green spots with black centers on the membranes, 35% had 20 to 99, and 17% had >100. With 195 brown eggs, approximately 80% had 0 to 19 spots on the shell membrane, 15% had 20 to 99, and 5% had >100.[22] About 80% of the brown eggs having from >80 to 100 black-centered spots on the shell membranes had no cuticle on the entire shell, cuticle on one pole only of the shell, or a grazed cuticle. The last fault was caused presumably when an egg with an immature cuticle was forced over the wire floor of a battery cage. Eggs of all three categories occurred (but at a very low incidence) in the 80% of brown eggs that had 0 to 19 spots per shell membrane. The outer orifices of some pores are evidently plugged even though a stain fails to demonstrate cuticle on the surface of the shell. With other eggs, large numbers of colored spots occur on the shell membrane even though the shell surface is deeply and evenly stained. Cuticle presumably bridges, rather than plugs, the outer orifice of a pore, the latter being flooded when the bridge collapses under pressure. The effectiveness of the cuticle can be undermined by the following:

1. Innate properties of hens. These can affect the quality of the cuticle on their eggs on a day-to-day basis[10] as well as a hen-to-hen basis.[24]
2. The quality of the shell upon which the cuticle is laid down. Thus, carbon black penetration of white eggs is commonly associated with calcareous lumps on the shell.[22] Alls et al.[2] noted that antibiotic penetration was most pronounced through "sandy" areas of a shell or in the region of lumps on the shell surface. Such lumps, which can be persistent features on eggs laid by particular hens, cause malformations in the pores in the adjacent shell.[123]
3. The conditions to which an egg is exposed before bacterial challenge. Thus, attrition between shell surfaces and nest floor or brushes in washing machines,[121] forced cooling,[42,49] choice of chemicals for egg washing,[78] and microfractures in the shell[28] all compromise the effectiveness of the cuticle.

The above discussion was based on a concensus view, namely that the cuticle-pore complex is the major barrier to trans-shell infection. This view, which had its genesis in the work of Haines and Moran,[62] has been challenged by Solomons and coworkers.[89,91,118] They claim that the translocation is influenced mainly by shell quality and the microstructure of the mammillary layer (Figure 24-2). The specific gravity of an egg (determined by immersing an egg in a series of sodium chloride solutions of increasing concentration and identifying the one that allows the egg to float) is closely correlated with shell quality, especially shell thickness.[126] Bacterial penetration of the shell of eggs having a specific gravity (SG) of 1.07 was greater than that of those with an SG of 1.08, and penetration of the latter was greater than in those with an SG of 1.09.[94] In practice these results may well reflect in part the influence of the drag factor of the pore canal in trans-shell infection; the thicker the shell (*viz.* eggs of SG 1.09) the greater the drag factor of the pore canal and, hence, the lower the probability of bacteria being translocated through the pore to the shell membrane.

Solomons and coworkers[121] found no correlation between bacterial penetration of the shell and pore numbers or quality of cuticle but a good correlation with various faults in the structure of the mammillary layer. It is not clear from these studies whether or not such faults caused malformation of pore canals arising at, or adjacent to, the malformed cones in the mammillary layer.

Eggshells are contaminated by contact with nesting materials, the hands of poultry workers, and surfaces in the packing/grading room.[19,107] The range in the level of contamination of eggs from one source can be very large *viz.* $3.0 \times 10^2 - 1.0 \times 10^7$ for clean grade A eggs taken from a packing station (Table 24-5). Gram-positive bacteria are commonly the dominant contaminants of egg shells (Table 24-6) whereas Gram-negative ones are the principal cause of rots in eggs (Table 24-3).

Although it is evident that we still have a poor understanding of the physics of water and particle transfer along pores in the eggshell, the available evidence has allowed effective egg-washing practices to be devised.[30] Implementation of the following measures[8] allows washing of table eggs with a minimum level of spoilage during storage. Likewise these measures ought to allow also effective sanitization of hatching eggs on the production farm, a practice that is intended to replace formaldehyde treatment of eggs at a hatchery:

1. Wash eggs soon after lay.
2. Ensure that the temperature of water used for washing and rinsing is at least 10°C above that of the eggs.
3. Use an approved detergent-sanitizer.
4. Include a sanitizer in the rinse water.
5. Routinely check the concentration of detergent-sanitizer in wash and rinse water.
6. Clean egg-washing machines daily.
7. Ensure that wash water has a low content of Fe^{+++} (aeration of water entering a distribution system ensures a low level contamination with

Table 24-5 Levels of Bacterial Contamination of the Shell of the Hen Egg

		Number of Microorganisms		
Source of Eggs	*No. of Eggs Examined*	*Mean*	*(Range)*	*Ref.*
Farm (handled with gloved hands)	36	9.5×10^3	(NG[a])	107
Farm (normal handling)	36	1.5×10^5	(NG)	107
Packing station	72	7.0×10^4	(NG)	19
Battery hens	25	2.2×10^4	(2.5×10^3–8.1×10^4)	19
Hens on deep litter	25	3.5×10^5	(6.2×10^3–2.4×10^6)	19
Shops and farms	96	3.1×10^6	(5.0×10^2–1.0×10^7)	
	130	1.3×10^5	(NG)	107
Packing station				
Clean Grade A	NG	2.2×10^5	(3.0×10^2–1.0×10^7)	19
Lightly soiled Grade B	77	9.7×10^5	(1.0×10^3–1.9×10^7)	19

[a]NG = Not given.

Table 24-6 The Microflora of the Shell of the Hen Egg

Organism	Eggs from Shops and Farms	Eggs from Packing Stations: Clean	Eggs from Packing Stations: Lightly Soiled	Eggs from Packing Stations: Cracked
Staphylococcus	5[a]	9	5	11
Micrococcus	18	37	52	42
Bacillus	30	–	2.5	–
Pseudomonas/ "*Achromobacter*"	25	24	14.5	25
Coli-aerogenes	5	10.5	7.5	4
No. organisms examined	100	130	164	126

the element; water taken directly from a bore hole and used without aeration may contain relatively high levels of Fe^{+++}).

8. Place washed and dried eggs in a chiller as soon as possible after washing.

24.7.2 The Lag Period

There is a lag period of 7 to >20 days between trans-shell infection of freshly laid eggs and gross contamination of their contents (Figure 24-5) during storage at ambient temperatures.[21] There is a lag also before the growth of salmonellas in eggs infected by the oviducal route.[75] There is no such period in eggs infected by the former route when bacteria are suspended in water containing >2 ppm Fe^{+++}.[15] The specific gravity (SG) of eggs influenced the duration of the lag period. Eggs with SG >1.082 showed signs of rot 8 days (on average)

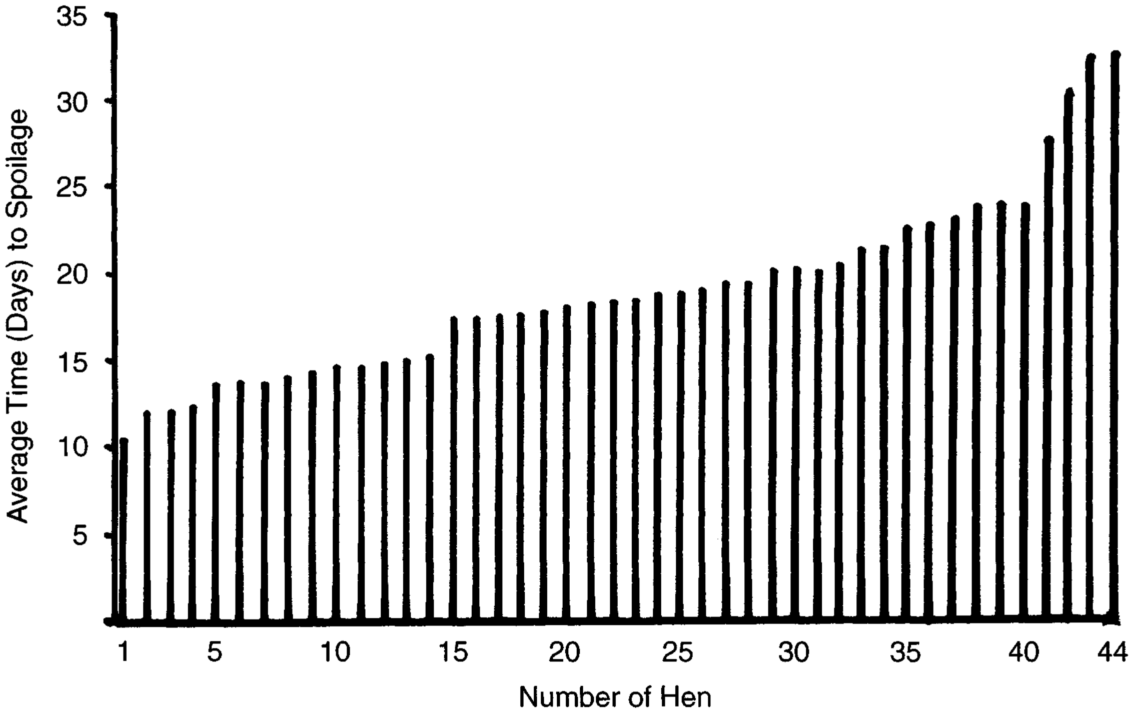

Figure 24-5 *Pseudomonas* Spoilage of Eggs Laid by Individual Hens. Eggs from Leghorn hens stored at 30°C for 24 hours. A chilled (5°C) culture of a fluorescent pseudomonad was poured over the warm eggs. After 10 minutes, the eggs were removed from the culture, dried and stored at 20°–21°C in a store having a relative humidity of 70% to 90%. On every third day during storage, the incidence of bacterial spoilage was established by candling with a UV lamp. Three or four eggs laid consecutively by individual hens were included in the experiment. *Source:* Adapted with permission from V. Orel, The Pseudomonas Spoilage of Eggs Laid by Individual Hens, *Poultry Science*, Vol. 36, pp. 8–12, © 1959, Poultry Science Association, Inc.

later than those having a lower SG.[94] The extent of bacterial penetration of the shell was greater in eggs of SG 1.07 than in those of SG 1.08. The shell's contribution to the defense appears to be determined also by the actual site of bacterial penetration (Figure 24-6). Thus, a far higher incidence of spoilage occurred in eggs challenged with bacteria after the pointed pole had been waxed *vis-à-vis* those whose broad poles had been waxed.[142] This must be considered in the context of the direction of movement of the yolk relative to the site of infection (see below).

It is obvious from Figure 24-7 that the albumen plays a central role in the antimicrobial defense of eggs. The duration of its contribution varied markedly (from 8 to 28 days; Figure 24-7) and is determined in part by the size of the microbial challenge. On average the lag was 9.9 days in eggs inoculated in the shell membrane with 6.0×10^5 pseudomonads but 22 days with an inoculum of 6.0×10^2.[27] There is also a marked variation in the duration of the albumen's defense when whole eggs broken out in plastic pots are inoculated with a piece of shell membrane infected with *S. enteritidis*.[83]

When various serotypes of *Salmonella* were inoculated into albumen (pH 9.2) alone, the majority failed to increase in numbers during 42 days' incubation at 20° or 30°C.[84] A few serotypes grew sluggishly throughout incubation. The addition of sufficient Fe^{+++} to saturate ovotransferrin in albumen induced rapid multiplication of all the serotypes, even those that had remained quiescent throughout 42 days' incubation. Large populations were formed within 24 hours at 25°C in albumen supplemented with ferric ammonium citrate alone or Fe^{+++} in combination with ammonium citrate. The addition of ammonium citrate and a range of growth factors had the same effect, but neither of these alone induced the growth of salmonellas. When depletion of glucose from albumen was used as an index of the effect of supplements,[34,35] the addition of Fe^{+++} and a source of combined nitrogen were essential for the rapid and complete removal of this substrate.

A lag period was a feature also in eggs inoculated with washings from dirty egg shells[112] or mixed cultures of bacteria isolated from eggs.[44] Gram-negative bacteria attained numerical dominance *vis-à-vis* Gram-positive ones in the shell membranes during this lag period. When rapid growth led to a generalized infection of the yolk and white, *Pseudomonas* spp. (probably because of their simple growth requirements) became dominant in eggs stored at ambient temperature or below, coliforms at 37°C.

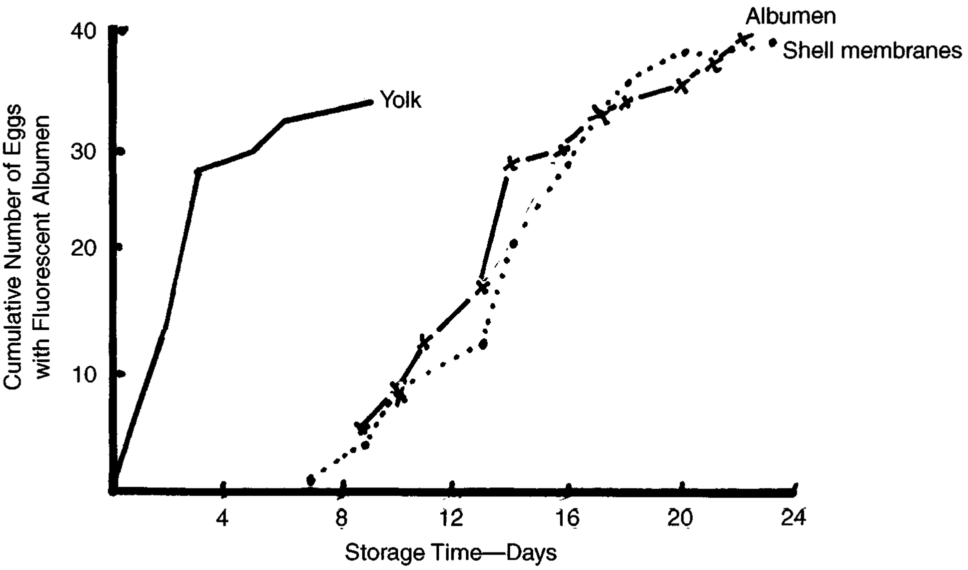

Figure 24-6 Influence of Infection Sites on the Rate of Bacterial Rotting of Hen Eggs. Eggs produced by Single Comb White Leghorn hens were washed on the day following lay in a detergent-sanitizer at 42°C. A washed suspension from an 18 to 24 hour culture of *Pseudomonas aeruginosa* (1.0×10^4 cells) was inoculated into the yolk, shell membrane, or albumen. Inoculated eggs were stored at room temperature and candled with a UV lamp. *Source:* Adapted with permission from W.E. Brown, R.C. Baker, and H.B. Naylor, Egg Spoilage as Affected by the Route of Exposure, *Poultry Science*, Vol. 45, pp. 279–283, © 1966, Poultry Science Association, Inc.

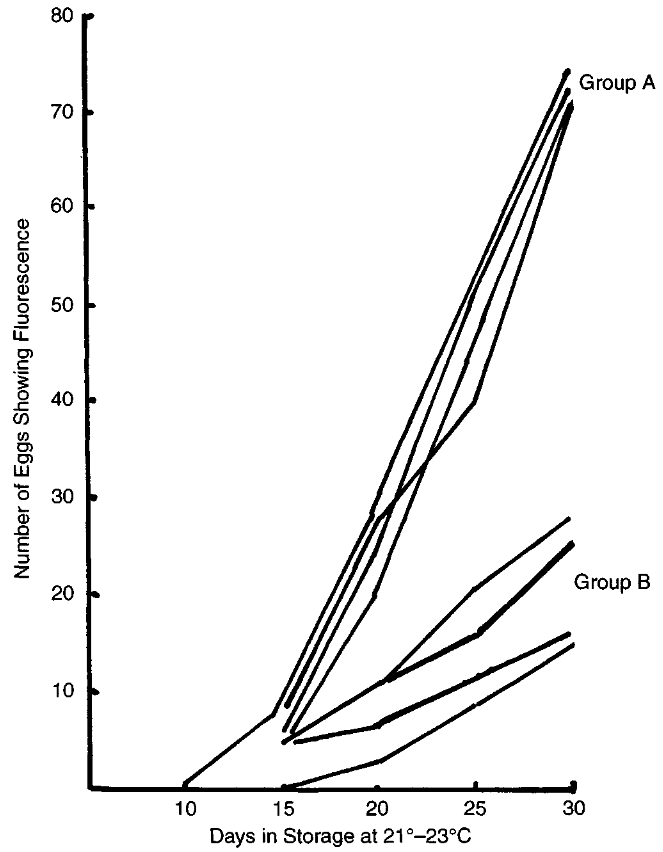

Figure 24-7 Influence of Infection Routes on Bacterial Rotting of Hen Eggs.[142] Eggs laid by White Leghorn hens were washed on the day after lay in a detergent-sanitizer (45°C), rinsed in water (40°C), and allowed to dry at room temperature. The eggs were dipped in paraffin wax (see below), warmed to 35°C, and dipped for 5 minutes in a suspension (1.0 ¥ 10^6 cells ml^{-1}) of *Pseudomonas aeruginosa* in water (15°C). Dipped eggs were stored at 21°–23°C and candled daily with a UV lamp. Very few eggs showed fluorescent whites until about 15 days of storage. Thereafter, the eggs divided into two groups. The eggs in Group A had not been waxed or waxed other than on their broad poles; eggs in Group B had been waxed entirely or on their broad poles. *Source:* Adapted with permission from D.V. Vadehra, Infection Routes of Bacteria into Chicken Eggs, *Journal of Food Science,* Vol. 35, pp. 61–62, © 1970, Institute of Food Technologists.

There is no lag period when there is >2 ppm iron in the inoculum.[15,35] This amount would have no effect on the chelating potential of the ovotransferrin in the albumen. In practice the iron impregnates the glycoprotein mantles on the fibers of the shell membranes, and there is a very slow migration into the underlying albumen.[135] Extensive bacterial growth occurs at the site of iron contamination of the membranes and heavy infection of the underlying albumen ensues.[15]

Seven hypotheses have been put forward to account for the lag period:

1. It is the time required by bacteria to penetrate the shell membranes.[57]
2. Initially, the shell membranes are an inimical environment. Some as yet uncharacterized change in the membranes at about 14 days postlay triggers bacterial growth not only on the membranes but in the underlying albumen.[26]
3. The lag period is terminated in eggs stored at room temperature when the upward movement of the yolk (Figure 24-4) is arrested by an infected shell membrane, leading to rapid bacterial growth.[16,34] This is the most likely interpretation of the data given in Figure 24-7. This particular hypothesis highlights the importance of the albuminous sac as a barrier to yolk movement and the many factors that contribute to its quality including the genetic make up of the hen,[31,132] nutrition,[76] stage in laying cycle,[126] health,[122] and storage conditions[108] of the egg, particularly temperature and relative humidity.[93]
4. The collision of quiescent contaminants of the albumen with the yolks in eggs infected with psychotrophic bacteria and incubated at chill temperatures.[20]
5. The synthesis of siderophores[59] by iron-deprived bacteria in the albumen triggers growth and generalized infection of the egg's contents.[15] If this hypothesis is invoked to explain salmonella growth in albumen, then an explanation is required for the failure to demonstrate siderophore production by coliforms in albumen *in vitro*.[134]
6. Some as yet uncharacterized change in the vitelline membrane accelerates the outward diffusion of nutrients and Fe^{+++} from yolk to white and facilitates bacterial penetration of the yolk.[75]
7. Bacteria in the albumen respond chemotactically to a gradient generated by diffusion of nutrients from the yolk. Some of the bacteria that make contact with the yolk begin to grow, and growth moves progressively outwards until the entire albumen is heavily contaminated with metabolically active, rather than quiescent, organisms some of which invade the yolk causing a generalized infection.[85]

It is noteworthy that the four most plausible hypotheses implicate the yolk in the termination of the lag period. Thus, under commercial conditions, and especially during extended storage at ambient temperatures, the very defense that has evolved to protect the yolk against microorganisms is negated by the yolk.

It is evident from the above discussion that many factors induce multiplication of quiescent bacteria in the albumen. This situation must be recognized by regulatory agencies, especially as no one event can be singled out as the critical factor. Thus, any regulation must recognize the enormous variation in the efficiency of the defense systems of eggs and adopt a storage period that easily accommodates such, and adopt storage conditions, especially chill storage, that ensure maximum retention of the antimicrobial properties of the most vulnerable eggs. In practice the recommendations of the Dick Committee[5] reflect both issues.

24.8 EGG PRODUCTS

In the US in 1992 about 25% (1.5×10^{10}) of all eggs were used to make egg products (total weight approximately 8.0×10^8 kg).[38] It has been predicted that by the year 2000, 50% of all eggs laid in the US will be used for this purpose[8]; the range of products will undoubtedly be large (Tables 24-7 and 24-14). There have been three phases in the evolution of the egg product industry in the US, the largest player in the market. Each had its attendant, and in most cases, unique microbiological problems. A discussion of these phases must take account also of the parallel evolution of the heat exchangers that were required for the dairy industry in order to prepare pathogen-free milk with a long shelf life at chill temperatures.

24.8.1 The Innovative Phase

In 1878, an American firm used a drying process to produce a light brown, meal-like substance from yolk and albumen. Frozen whole eggs (white and yolk not mixed) were prepared commercially in the 1890s.[38] The Maillard reaction between glucose and protein impaired the functional properties of dried egg products.[111] Glucose oxidase or microorganisms, most commonly *Klebsiella pneumoniae,* are used to remove glucose from albumen, whole egg, and yolk prior to drying (Exhibit 24-1). Impairment[39] of the functional properties of yolk stored at ≥ –6°C is prevented by the addition of salt or sugar before freezing (Table 24-7). Such amendments enhance the thermal tolerance of contaminants. This is reflected in the time/temperature combinations that have been adopted to inactivate salmonellas in salted or sugared egg yolk (Table 24-9).

Table 24-7 Major Types of Egg Products and Their Uses

Product	*Examples of Major Use*
Whole egg	
Frozen	Baked goods, institutional cooking, mayonnaise
Dried[a]	Above plus ice cream manufacture; preparation of dry mixes for cakes, etc
Liquid, extended shelf-life products	1 kg cartons or larger amounts in "bag-in-box" packs for use by bakers, caterers, home bakers, etc; shelf life of 28 days with storage at 4°C
Albumen	
Chilled (storage life *ca.* 4 days at 4°C)	
Frozen[a]	Baked goods, icings, chocolate
Dried[a]	
Yolk	
Frozen	
plain[b]	Baked goods, noodles, ice cream
salted	Salad dressings, soups, mayonnaise
sugared	Baked goods, eggnog, ice cream
dried[a]	Dry mixes for cakes, mayonnaise, macaroni
Chilled, liquid with extended life (28 days at 4°C)	1 kg cartons or larger amounts in "bag-in-box" for use by bakers, caterers, home bakers, etc

[a] Glucose must be removed before freezing and drying (methods given in Exhibit 24-1).

[b] There is an increase in viscosity and eventually gelation of plain yolk stored ≥ –6°C. This can be prevented by addition of salt or sugar (commonly at 10% concentration) to yolk before frozen storage.

Bruce, Effect of Processing on the Microbiology of Eggs, in *Microbiology of the Avian Egg,* R.G. Board and R. Fuller, eds., pp. 153–173, © 1994, Chapman and Hall.

Cotterill[38,39] noted that growth in the frozen egg industry in the 1920s and 1930s was not accompanied by much in the way of technical innovation. It was recognized, of course, that the microbiological quality of a product would be determined by the treatment of eggs prior to and immediately following breaking. A regime based on common sense was adopted in order to minimize contamination of products as follows: (1) eggs were candled to eliminate rots; (2) egg shells were washed (sometimes with disinfectants) so that small fragments falling into whites when broken did not cause gross contamination; (3) every egg was broken manually into a small

Exhibit 24-1 Methods Used to Remove Glucose from Albumen, Whole Egg, and Yolk Prior to Drying

1. **Reasons for and methods of desugaring albumen**
   - Maillard reaction (initially a bonding of glucosidic hydroxyl groups and amine groups of peptides) causes brownish discoloration of dried albumen. Albumen also loses solubility and acquires metallic off-flavor.
   - Glucose can be removed by
     - Spontaneous microbial fermentation—traditional method especially in China, which was used until mid-1940s.
     - Controlled bacterial fermentation (the most commonly used method) of the many organisms studied, a strain of *Klebsiella pneumoniae* has been generally adopted by the industry.
     - Yeast fermentation—3-hour fermentation at 37°C with strains of *Saccharomyces*; eg, *S. cerevisiae.*
     - "Enzyme" fermentation[a]—glucose oxidase used to convert glucose in albumen to gluconate and catalase to break down H_2O_2.
2. **Reasons for and method of desugaring whole egg and egg yolk**
   - Maillard reactions occur (see above); additionally, reaction of glucose with phospholipids, especially cephalin, causes discoloration of dried whole egg or egg yolk powder.
   - Glucose oxidase and catalase system used almost exclusively to remove glucose with incubation at 10°C in order to deter growth of undesirable microorganisms.

container and inspected by the egg breakers; 12 or 10 eggs in a larger container were inspected by a supervisor before addition to a bulk tank; and (4) equipment contaminated with a rotten egg was removed from the production line, washed, and sterilized. Such labor-intensive methods, which may well still be practiced in developing countries, were no doubt essential in the days when egg product manufacturers had to buy eggs on an open market supplied by small farms or from chill stores. In the author's experience, this regime produced whole egg of reasonable microbiological quality. Poor plant hygiene led to a pasteurized product that acquired a custard-like character if left overnight at room temperature. This was caused by lecithin breakdown by *Bacillus cereus.* All the faults associated with "bitty cream" formation in pasteurized milk (see Chapter 22) were present in the egg-breaking plant.

As the industry grew, so did the demand for mechanical egg breakers.[40] It is common for such machines to be included in a production line: bulk candling of eggs → washing of egg shells → egg breakers. Inspection of broken-out eggs is commonly done by a person sitting alongside a gully taking the eggs to a bulk tank. It was not uncommon to see eggs with green fluorescent whites go unmolested along the gully. This was due to fatigue and/or boredom of an inspector. The problem was exacerbated also by the need for egg-breaking plants to use eggs that had been stored for long periods. It is evident from the above that flocks of hens dedicated to the needs of an egg processor are required for the preparation of products having low levels of microbial contamination.

24.8.2 Pasteurization

The outbreak of World War II saw a dramatic increase in the demand for dried, whole egg, and it was realized that this product could transmit salmonellas from poultry, which showed no clinical symptoms of infection, to man. Thus, according to a report in 1947, 5 of 43 samples (5-oz packs) of spray-dried egg in the UK intended for home use contained salmonellas. Such packs were often associated with family outbreaks of food poisoning.[3] Many other surveys, reviewed in 1971,[80] showed the incidence of contamination of egg products with salmonellas; for example, 0.3% of 1,649 samples of untreated or chilled liquid egg in England, 2.6% of 786 samples of frozen egg in England, 5% of 39,502 samples of egg products imported into Germany in 1956, and 1.9% of 4,586 samples of liquid egg taken from approximately 30 processing plants in the UK. After the introduction of pasteurization of egg products in the UK, no salmonellas were recovered from 5,980 samples of pasteurized liquid egg or from 11,600 samples of dried egg from the 30 processing plants referred to above.

Pasteurization of whole liquid egg and egg yolk was used first in some parts of the egg product industry in the 1930s.[41] Regulations requiring mandatory pasteurization were introduced in the UK in 1963 and in the US in 1966. Several types of processes are used now to reduce the numbers of microorganisms in liquid egg products (Table 24-8). Many liquid egg products are pasteurized by a high-temperature-short-time (HTST) method, giving a product with a shelf life for whole liquid egg at 4°C of usually up to

7 days, and for salted egg products of up to 4 weeks. An alternative HTST pasteurization method (ultrapasteurization), which was developed in 1985–1987, is used for products that are packed aseptically and are required to have an extended storage life, possibly of 3 to 6 months at 4°C,[9] but in practice often up to 10 weeks. The conditions specified for pasteurization of egg products in the UK, the US, and in the Codex Alimentarius are shown in Table 24-9.

Continuous HTST pasteurization systems heat the liquid egg rapidly to the required temperature and maintain it at that temperature for a specified period of time, by the use of holding tubes of appropriate lengths. The equipment requires control systems to regulate the rate of flow.

The major objective of the heat treatment used for pasteurization was to inactivate the main types of salmonella found in egg products and to minimize the damage to the functional properties of egg. Studies in the 1960s and 1970s of the heat resistance of *Salmonella* spp. in liquid egg indicated that the conditions specified for pasteurization of whole liquid egg would be sufficient to reduce the number of viable salmonellas in the product by 1,000- to 10,000-fold.[47] Rare strains of salmonella occur that would not be destroyed by this treatment. The main strain is *S. senftenberg* 775W, which was isolated from eggs in 1946; among hundreds of isolates from eggs tested in the subsequent 30 years neither this strain nor another strain with comparable heat resistance was found again. In the late 1950s the decision was made that the quality of the pasteurized product should not be sacrificed by the application of a heat treatment that would be required to inactivate a strain that occurred so rarely.[47] The regulations for pasteurization were introduced before *S. enteritidis* became a major problem in eggs, but general experience has been that pasteurization has proved to be effective in preventing the transmission of *S. enteritidis* in egg products.

The heat treatment specified in the UK and in the Codex Alimentarius for liquid whole egg and egg yolk also destroys the activity of α-amylase. This enables a test for α-amylase activity to be used to indicate whether effective pasteurization has been carried out. This enzyme is not inactivated by the minimum heat treatment specified for pasteurization of liquid whole egg in the US (60°C for 3.5 minutes) and no suitable enzyme test is available in the US to determine whether an adequate HTST pasteurization treatment has been applied.[41]

The presence of high concentrations of salt (NaCl) or of sugar (sucrose) in egg products lowers the water activity of the product and protects bacteria against heat treatment, raising their apparent heat resistance. For this reason greater heat treatment is specified for such products. In addition to protecting salmonellas from heat treatment an NaCl concentration as high as 10%, used in some products, would prevent growth of any surviving salmonellas, which would die gradually.[47]

Egg white is much more sensitive to heat treatment than are other egg products; it can be pasteurized at lower temperatures because salmonellas are

Table 24-8 Processes Used To Reduce the Numbers of Microorganisms, Especially Salmonellas, in Liquid Egg Products

Process	*Comments*
Holding method of pasteurization (batch process)	Developed in the 1930s–1940s. Experiments showed that heating whole liquid egg to 57°C, with a 30 min heat-up time, and holding at 57°C for 6 min reduced the number of viable *S. typhimurium* by a factor of at least 10^6.[41] This method is seldom used now in the UK or the US.
High-temperature-short-time (HTST) pasteurization	Times and temperatures shown in Table 24-9. The storage life of liquid whole egg at 4°C is usually 4 to 7 days; that of salted egg products is up to 28 days. This is a major method used for preservation of liquid egg products.
Alternative pasteurization, "ultrapasteurization"	Developed in 1985–1987. This uses higher temperatures than the minimum specified for pasteurization; products are then packed aseptically and the storage life at 4°C is usually up to 10 weeks. This method is used for a significant proportion of egg products in the UK, and its use is increasing.

Table 24-9 Minimum Heat Treatments Specified for Pasteurization of Liquid Egg Products

Product	*Temperature*		*Minimum Holding Time (minutes)*	*Reference*
Whole liquid egg	64.4°C		2.5	36, 131
	60°C	140°F	3.5	139, 140
Egg yolk	64.4°C		2.5	131
	61.1°C	142°F	3.5	139, 140
	60°C	140°F	6.2	139, 140
Egg albumen	57.2–57.8°C		2.5–3.0	131
	56.7°C	134°F	3.5	139, 140
	55.6°C	132°F	6.2	139, 140
Whole egg with 2% more NaCl	63.3°C	146°F	3.5	139, 140
	62.2°C	144°F	6.2	139, 140
Whole egg with 2–12% sucrose	61.1°C	142°F	3.5	139, 140
	60°C	140°F	6.2	139, 140
Egg yolk with 2–12% NaCl	63.3°C	146°F	3.5	139, 140
	62.2°C	144°F	6.2	139, 140
Egg yolk with 2% or more sugar	63.3°C	146°F	3.5	139, 140
	62.2°C	144°F	6.2	139, 140

more heat sensitive at the higher pH of egg albumen than at the lower pH in other egg products. In the past the pH of egg white was usually about 9;[47] the pH can be between 7.6 and 9.3, with a range commonly between 8.4 and 9.2.[8] As a result of the more rapid transport of eggs from the laying site to the processing operation in North America, the pH of commercial liquid egg white is often at or below pH 8.2.[98] This decrease in pH of egg white increases the heat resistance of *Salmonella* spp.; time-temperature treatments for pasteurization of raw egg white at various pH levels have been published.[41]

Alternative processes have been devised for pasteurizing egg white without impairing its functional properties, in particular "whippability," an essential commercial attribute of egg albumen (Exhibit 24-2).

The alkalinity of egg white (commonly pH ≥9.0; Figure 24-4) accentuates heat damage to proteins present and thermal destruction of salmonellas.[33] The majority of the oviductal proteins (Table 24-1) have a maximum stability at pH 7.0. Ovotransferrin (conalbumin) is the exception but its stability is enhanced by the formation of a complex with aluminium. Albumen adjusted to pH 7.0 and supplemented with Al^{4+} requires pasteurization at 60° to 62°C for 3.5 to 4.0 minutes.

Exhibit 24-2 Alternative Methods Proposed for Pasteurization of Egg White without Impairment of Its Functional Properties[a,b]

Lactic Acid plus Aluminum Sulfate Process

Lactic acid is used to reduce the pH of liquid egg white to about 7.0. At this pH the heat stability of most egg white proteins is increased. The major exception is ovotransferrin; this is rendered less heat-labile by the addition of aluminum, forming a complex with ovotransferrin. Egg white treated in this way can be pasteurized in the US at 60° to 62°C for 3.5 to 4 minutes. The process is governed by US government patent; fee-less licenses have been granted to more than 45 firms in the US.

Heat plus Hydrogen Peroxide (Armour Process)

Liquid albumen is heated to not less than 125°F in a plate pasteurizer and maintained in holding tubes for at least 1.5 minutes. Hydrogen peroxide, at least 0.05%, is injected into the liquid albumen, which is maintained at 125°F for a further period of not less than 2 minutes. The product is then cooled and pumped to a drawoff or holding vat, where catalase is added to remove residual hydrogen peroxide. This method is widely used in the US.

Heat plus Vacuum Process

This method requires an HTST pasteurizer equipped with a vacuum chamber. Liquid egg white is maintained in the vacuum chamber for 17–20 minutes before heat treatment at 57°C (134°F) for 3.5 minutes. The vacuum treatment removes air bubbles from the albumen. This method has been approved by the US Department of Agriculture (USDA).

Hot Room Process

Dried, powdered albumen is stored at 53° to 65°C for between 5 and 20 days; this reduces the numbers of salmonellae without impairing functional properties.[c]

[a] Based on Cunningham[41] and USDA.[139]

[b] Lysozyme (for use as an antimicrobial agent in the dairy industry) may be extracted by acidic ion exchange resins before processing. Extraction has a minimal effect on the functional properties of egg white.

[c] Banwart and Ayres.[11]

Storage of dried, powdered albumen at 53° to 65°C for between 5 and 20 days is used to reduce the number of salmonellas without impairing functional properties of the albumen (Exhibit 24-2). Other processes that have been used in the US are also shown in Exhibit 24-2.

Following the general recognition, in the early 1980s, that outbreaks of listeriosis resulted from foodborne transmission of *Listeria monocytogenes,* and that this bacterium can multiply at temperatures of 5°C and lower, attention has been directed to the incidence and survival of *L. monocytogenes* in egg products. *Listeria* spp. are occasional contaminants of egg processing plants and of egg products. Sampling of in-line filters in an egg processing plant on a daily basis for 5 months showed that 125 of 133 samples contained either *L. innocua* (62.2%) or *L. monocytogenes* (37.8%).[88] A mean level of listeria of one per ml of whole egg immediately before pasteurization was reported; no listerias were detected in 500 daily samples of pasteurized egg product. In a nationwide survey in the US of commercially broken, unpasteurized liquid whole egg *L. innocua* was isolated from 15 of 42 samples and *L. monocytogenes* was also isolated from 2 of these 15 samples.[81] The level of contamination with *L. monocytogenes* was estimated as between 1 and 8 cfu ml^{-1}. Following inoculation into raw egg products, a strain of *L. monocytogenes* multiplied in egg yolk at 5°C, showed a slight increase in whole egg, but died out in egg white.[118] At 20°C multiplication of the listeria occurred in egg yolk, whereas in liquid whole egg a 2-log reduction in numbers during the first 24 hours was followed by slow growth. The bacterium died in egg albumen at 20°C. After heating at 121°C for 15 minutes, egg yolk, liquid whole egg, and albumen all supported relatively rapid growth of *L. monocytogenes* at 20°C and at 5°C.

Because of the risk posed by *S. enteritidis* in eggs and the reported incidence of *L. monocytogenes* in egg products, in the 1990s attention has been directed to the effect of heat treatment on the survival of these bacteria in egg products (Tables 24-10 and 24-11).

In a study of 17 strains of *S. enteritidis,* including strains from patients and from egg-associated outbreaks of salmonellosis, after growth at 37°C the D-values at 60°C in liquid whole egg were between 11.8 and 31.3 seconds.[114] The authors stated that on the basis that the true residence time at 60°C for whole liquid egg in a 3.5 minute average holding tube was 2.83 minutes, pasteurization would give a 5.4-D process for their most resistant strain. Sublethal heat shock at 40°C for 2 hours or 48°C for 30 minutes increased the heat resistance 2- or 3-fold. It was calculated that pasteurization at 60°C would give approximately a 4-D kill of *S. enteritidis* with induced thermotolerance, but the authors pointed out that with the use of good manufacturing practices it would be unlikely that thermotolerant salmonellas would be present in commercial liquid egg.[114]

Palumbo et al.[97] used submerged vials to investigate the heat resistance of *Salmonella* spp. and *L. monocytogenes* in liquid egg yolk and egg yolk products; because any lethality during the heating up of the vials apparently was not measured, it would be expected that the D-values reported would be underestimates.

Using a mixture of three strains of *S. enteritidis* and two strains of *S. typhimurium,* grown at 37°C, and an immersed, sealed capillary tube technique, Schuman and Sheldon[109] reported mean D-values in raw liquid egg yolk (pH 6.3) of 0.28 minutes at 60°C and 0.087 minutes at 62.2°C. In egg white pH 8.2 and pH 9.1 the D-values at 56.7°C were 2.96 minutes and 1.54 minutes, respectively.

The results in Table 24-10 indicate that the heat treatments specified in Table 24-9 for pasteurization for whole liquid egg, for egg yolk, and for egg yolk with 10% sucrose should give at least a 4–5 log kill of *S. enteritidis.* The conditions specified for pasteurization of egg yolk with 10% NaCl would have little effect on *S. enteritidis* (or probably on other salmonellas); although these organisms may survive in the product they would be incapable of multiplication and would die slowly. The conditions specified for pasteurization of egg albumen would cause limited inactivation of *S. enteritidis* in egg white at pH 8.2 but would be more effective in the product at pH 9.1. Previous studies showed also that the heat resistance of salmonellas in stored albumen (pH 9.0) was about half of that in fresh albumen (pH 8.0).[37] Recommended pasteurization temperatures for raw egg white at different pH levels have been published[41] or egg white may be aged slightly or the pH adjusted chemically[109] to improve the bactericidal effect of pasteurization.

The results in Table 24-11 indicate that the conditions specified in the US for pasteurization of whole liquid egg and egg yolk may only give a low kill of *L. monocytogenes,* whereas the conditions specified in the UK and by the Codex Alimentarius would be more effective. Conditions specified for pasteurization of products with 10% NaCl would have little effect on *L. monocytogenes.* At high temperatures *L. monocytogenes* may multiply in this concentration of NaCl, and the pasteurized product should be maintained below 5°C, which will prevent this.[48] Pasteurization of egg albumen would have little effect on *L. monocytogenes,* but the organism will tend to die out in this product at high pH.[48]

Source: Data from J.P. Erickson and P. Jenkins, Behaviour of Psychotrophic Pathogens *Listeria monocytogenes*, *Yersinia enterocolitica*, and *Aeromonas hydrophilia* in Commercially Pasteurized Eggs Held at 2, 6.7 and 12.8°C, *Journal of Food Protection*, Vol. 55, pp 8–12, © 1992, International Association of Milk, Food and Environmental Sanitarians, Inc. (IAMFES)

It should be emphasized that there appear to have been no reported outbreaks or cases of listeriosis associated with egg products; this may be because the incidence and numbers of *L. monocytogenes* in these products are low and in those products where pasteurization has least effect on listerias any surviving organisms are unable to multiply. The other psychrotrophic pathogenic bacteria, *Yersinia enterocolitica* and *Aeromonas hydrophila,* are less heat resistant than *L. monocytogenes* and are, therefore, less likely to survive pasteurization of egg products. These three psychrotrophic bacteria can multiply in some pasteurized egg products stored at low temperature, depending on the pH and the salt content of the product[48] (Table 24-12).

The unsalted egg products in Table 24-12 all showed spoilage, due to pseudomonads, or to *Serratia* spp. and coliforms, in 10–14 days; this might prevent the use of products in which growth of pathogens had occurred. The liquid whole egg containing 5% NaCl stored at 2°C and 6.7°C was not spoiled in this time, but after storage at 12.8°C for 14 days spoilage due to fecal strepococci and micrococci was reported. Thus, post-pasteurization contamination of egg products could result in multiplication of psychrotrophic, pathogenic bacteria, but with properly controlled refrigerated storage at ≤5°C for 5 to 10 days and hygienic conditions the risk was judged to be minimal.[48]

The adoption of pasteurization of whole liquid egg killed many spoilage bacteria as well as pathogens, giving a reduction in viable count of the order of 5 × 10^3 g^{-1}.[100] This caused an important change in the industry in that chilled liquid egg could be delivered directly to the bulk users, reducing the need for freezing or drying egg products. Pasteurized whole liquid egg was rarely, if ever, available in small packs for use in the home or institution, but this form of marketing became feasible with the introduction of alternative methods of pasteurization at higher temperature.

An alternative pasteurization procedure, termed by the originators of the process "ultrapasteurization," was developed in the mid-1980s. The process used high-temperature-short-time heat treatment at temperatures between 63.7°C and 72.2°C followed by aseptic packaging, and aimed to provide a product with an extended shelf life, under refrigeration, of 3 to 6 months and with an acceptable functional quality.[9] The most severe heat treatments used by Ball et al.[9] were equivalent to heating at 71.5°C for 36.5 seconds or at 71.8°C for 62.5 seconds. These treatments were reported to give shelf lives of at least 20 to 24 weeks at 4°C. Typical temperatures and holding times used for ultrapasteurization are shown in Table 24-13. In the UK a significant proportion of liquid egg products is produced by ultrapasteurization and the use of this process is increasing. In order to produce a satisfactory final ultrapasteurized

Table 24-13 Typical Temperatures and Times Used for Alternative Pasteurization (ultrapasteurization) of Liquid Egg Products

Product	Temperature (°C)	Holding Time (Minutes)
Liquid whole egg	69	1.5
Liquid yolk	65.5	5.0
Albumen	57	5.0

Table 24-14 Value-Added Egg Products[a]

Product	*Comments*
Hard-cooked eggs	Hard-boiled eggs have shells removed manually or mechanically and are packed (sometimes following immersion in boiling water or exposure to steam) in an acid solution containing a preservative *viz.* 0.2%–0.85% citric acid with 0.1% benzoate. Packed eggs are stored at approximately 0°C. Alternatively the eggs can be repacked after 4 days in a fresh solution of citric acid and benzoate and heat treated (boiling water for 20 minutes or steam at 121°C for 15 minutes). Stadelman et al.[129] found yeasts and mold growth on hard-cooked eggs after storage at 4° or 22°C for 1 week. Oblinger and Angalet[92] reported rapid bacterial growth and slime production in hard-cooked eggs stored at 25°C.
Diced egg[b]	Eggs broken into large trays, cooked in steam, diced while hot, and packed hot (82°C). Very limited microbial contamination, hence long shelf life at chill temperatures.
Hard-cooked egg[b] roll	Yolk surrounded by white in a polypropylene tube is cooked at 93°C for 20 min. Apparently, there are no microbiological problems during storage.
Scrambled eggs[b]	Eggs are scrambled, cooked, and packed hot (82°C) in appropriate containers for institutional use. The shelf life at the recommended storage temperature of 2°C is upwards of 45 days. It has been claimed that with use of pasteurized whole egg and Good Manufacturing Practice (GMP), there are no problems due to bacterial contaminants.
Frozen omelettes	Omelettes (either plain or filled) are sealed in plastic packs and frozen by cryogenic techniques in order to prevent ice-crystal damage to product.
Low-fat, low-cholesterol egg yolk[c]	Fat and cholesterol extracted from dried egg yolk using supercritical CO_2. As it is made from USDA certified pathogen-free ingredients and is manufactured with GMP under USDA supervision, problems with bacterial pathogens will be a very low risk.

[a]Development of value-added products discussed by Baker and Bruce[8] based on Stadelman.[127]
[b]Baker and Bruce.[8]
[c]Bringe and Cheng.[25]

product with ≤10 bacteria ml^{-1}, it is necessary to use good quality eggs that are very fresh and to pay critical attention to the cleanliness and hygiene of processing equipment. In the studies by Foegeding and Stanley[52] *Bacillus circulans* and *Enterococcus faecalis* were the most heat-resistant bacteria isolated from ultrapasteurized egg.

24.8.3 Value-Added Egg Products

A selection of value-added egg products is listed in Table 24-14. In practice, these commodities can be considered to be basically cooked or partially cooked high-protein items. As there is as yet little information about the storage history of such items it would appear sensible to adopt Good Manufacturing Practice developed for the preparation, distribution, and storage of cooked meat products.

24.9 THE FUTURE

The above discussion of ultrapasteurized and value-added egg products highlights the possible role of eggshells in transporting salmonellas from the laying hens to the processing plant. From a review of the literature, Humphrey[71] reported the following incidences of *Salmonella* contamination of the shells of eggs associated with human cases of food poisoning: 0% of 760, 1.1% of 372, 5% of 68, and 5.2% of 194 eggs. An incidence of shell contamination of 0.5% was reported for 998 eggs not associated with food poisoning. At first sight, these incidences might be considered to be insignificant. They are not, however, when considered in the context of the vast number of eggs used by the manufacturers of egg products. Indeed, it is evident that egg reception areas ought to be physically separated from egg processing

Exhibit 24-3 Practices with Potential To Bolster and/or Compromise the Safety of Ultrapasteurized or Value-Added Egg Products

Practices having the potential to bolster safety

1. Selection of layers that produce a well-defined albuminous sac, a low incidence of shell faults, and a high incidence of deposition of quality cuticle over the entire surface of an egg shell.
2. Use of eggs from dedicated flocks housed under conditions that minimize exposure to salmonellas.
3. Choice of an appropriate egg-washing regimen and the selection of detergent/sanitizers that do not damage cuticle integrity but effectively kill salmonellas on shell surfaces and impede cross-contamination.[33,42,49,78]
4. Pulsed light (8 flashes at 0.5J cm^{-2} per flash (for total treatment of 4J cm^{-2}) gave an 8-log kill of *Salmonella enteriditis* on surface of egg shell.[46]
5. Pasteurization of intact shell eggs.[70,130] A combination of heating whole eggs in a water bath (57°C for 25 minutes) and hot air oven (55°C for 60 minutes) gave a 7 log reduction in the numbers of *Salmonella enteriditis* in deliberately inoculated eggs.

Practices having the potential to compromise safety

1. Washing warm eggs in cold water containing ≥ 2 ppm Fe^{+++}.
2. Using the contents of eggs with cracked shells.[141]
3. Using eggs that have been stored for unknown periods at unknown temperatures.
4. Inadequate separation of egg reception (the dirty area) from egg processing (the clean area).

in plants producing ultrapasteurized or value-added egg products. Such separation ought to go some way toward guarding the finished product from cross-contamination. In addition, some or all of the factors listed in Exhibit 24-3 might well be considered.

25.1 INTRODUCTION

Vegetables and vegetable-based foods are normal parts of the human diet and are consumed daily in large quantities in most civilizations. Vegetable crops are grown in environments widely open to multiple sources of microbial contamination, the main sources being air, soil, and water. The influence of microorganisms on vegetables is part of everyday life. Spoilage of vegetables is visible daily in domestic refrigerators. Large-scale microbial spoilage had tragic and historic consequences. Thousands of Irish people died from starvation or left Ireland for America in the mid-nineteenth century, after the massive and disastrous attack on potatoes by the fungus *Phytophthora infestans*. Warnings about the consumption of raw vegetables in developing countries and reports of outbreaks show that vegetables may transmit human pathogenic microorganisms. Nevertheless, the majority of vegetables consumed are sound and free from hazards.

After harvest, vegetables can be considered as food products, but fresh vegetables continue to be living plant tissue. This tissue is compartmentalized by structures that limit the diffusion of solutes and this influences the survival and growth of microorganisms. In considering the interactions between microorganisms and vegetables, this compartmentalization must be taken into account. Vegetables may contain chemical compounds that inhibit microorganisms and may also produce defense reactions, similar to those formed by growing plants, against microbial invasion.

Vegetables present contrasting features, depending on the botanical organs. The post-harvest life of leaves, flowers, or fruits normally leads to senescence in contrast to that of storage organs like bulbs, tubers, and roots. Vegetables are also processed to make them more palatable or more stable than the raw ones. This processing has a lethal effect on vegetable tissue and modifies the microflora of vegetables and its behavior. Some specific aspects of the microbiology of processed cooked, dehydrated, and frozen vegetables will be considered.

This chapter will give an account of the diverse microflora of vegetables, the biological relations with the plant organ, and illustrate the consequences on the quality and safety.

25.2 THE MICROBIOLOGY OF RAW VEGETABLES

25.2.1 Numbers and Types of Microorganisms on Raw Vegetables

Numbers of Microorganisms

The number of aerobic mesophilic bacteria reported on vegetables varies between 10^2 and 10^8 cfu g^{-1} (Table 25-1). It varies among the various kinds of vegetables; the highest counts were found on salad sprouts and the lowest on vegetable fruits or on the inner leaves of cabbage heads. Counts are also extremely variable among samples from the same veg-

Table 25-1 Numbers of Aerobic Mesophilic Bacteria Found in Fresh Vegetables

Vegetable	*Place of Sampling*	*Aerobic Mesophilic Bacteria (log cfu g^{-1})*[a]	*Incubation Temperature of Media (°C)*	*Reference*
Leafy vegetables				
White cabbage	Field	2.7 to 5.0 for outer leaves	10 + 20	202
	Retail	6.0	28	281
Cabbage	Field and retail[b]	4.0 to 8.0 for 82% of samples	37	197

etables. Variations within a survey, among samples of the same vegetables, may reach 4 log units.[197,487] It is therefore difficult to draw general features.

This variability may reflect the great diversity of conditions prevailing during cultivation and post-harvest life of vegetables. The high counts found on shelled green peas[457] may result from post-harvest contamination. However, hydroponically grown vegetables are not less contaminated than field grown products (Table 25-1) and numbers of bacteria on vegetables sampled at retail were not different from those sampled in the field.[197] Counts are usually obtained on general media incubated between 20° and 30°C, except for some authors[197] who incubated media at 37°C. This was probably above the optimum growth temperature of many bacteria from vegetables and could have led to a slight underestimation of the total number of bacteria. For instance, among incubation temperatures ranging from 4° to 35°C the highest number of bacteria from cabbage leaves were counted on plates incubated at 20°C.[281] On celery[426] and lettuce[382] bacterial counts from plates incubated at 22°C exceeded those from plates incubated at 37°C by 1 or 2 log cyles. The optimum growth temperature of strains of pseudomonads isolated from vegetables was between 25° and 30°C.[92]

Types of Microorganisms

The majority of Gram-negative rods identified from raw vegetables were fluorescent pseudomonads, *Enterobacter* spp., *Klebsiella* spp., *Serratia* spp., *Flavobacterium* spp., *Xanthomonas* spp., *Chromobacterium* spp., and *Alcaligenes* spp.[86–88,281,358,364,473,507] Gram-negative rods were predominant among isolates from a range of vegetables[473] such as broccoli,[364] cabbage,[281] endive,[507] mungbean sprouts,[358] and carrots.[502] An important proportion of isolates from broccoli were coryneform bacteria[87] and catalase-negative cocci predominated in raw peas and raw sweet corn.[473] In India, the mesophilic microflora of potatoes mainly comprised Gram-positive bacteria, *Bacillus* spp., *Micrococcus* spp., and *Sarcina* spp.[210]

Selective and diagnostic media have been used to differentiate the main groups of bacteria found on vegetables (Table 25-2). Selective media for enterobacteria may prevent growth of some strains and underestimate their numbers as found on tomatoes[86]; counts on selective medium were 2 log units lower than on the nonselective medium for mesophilic bacteria, whereas enterobacteria represented at least 10% of the mesophilic bacteria counted on the nonselective medium. Pectolytic microorganisms are frequently enumerated to estimate the number of microorganisms that could cause spoilage, because the enzymic breakdown of pectic polymers in the plant cell wall is the main cause of maceration and soft rot development.[315] Pectin degradation is revealed on pectin-based media, either by chemical reagents[443] or by the formation of pits in the pectate gel.[141,393] Pectolytic bacteria have been identified as fluorescent pseudomonads, *Cytophaga* spp., *Flavobacterium* spp., *Xanthomonas* spp., and *Erwinia* spp. Among lactic acid bacteria, *Leuconostoc mesenteroides* was the most frequent and the most abundant species found on vegetables (Table 25-2). A majority of isolates (70%) produced slime on sucrose medium,[374] a trait that may be important in spoilage of some processed vegetables.

The number of yeasts and molds found on various raw vegetables was between 1 and 5 log cfu g^{-1},[86,87,202,280,281,455,456,457] although cfu is probably not appropriate to quantify molds. Yeasts identified belonged to the genus *Cryptococcus, Candida, Rhodotorula,* and *Sporobolomyces*.[148,202] Molds belonged to the genus *Cladosporium, Aureobasidium, Aspergillus, Penicillium, Phoma, Botrytis, Fusarium, Epicoccum,* and *Geotrichum*.[78,202]

Microorganisms of Public Health Significance

Information about bacterial indicators of fecal contamination on raw vegetables is abundant, but most data concern fecal coliforms cultivated at 44°C. Their value as fecal indicators is poor[89,317,473] because many bacterial species, normally present on the surface of vegetables, give positive results on media for fecal coliforms. For instance, on carrots, only 2% of isolates from plates for fecal coliforms (incubated at 44°C) were identified as *E. coli*, while the majority of isolates were identifed as *Enterobacter aerogenes, E. amnigenus, E. sakazakii,* and *Klebsiella pneumoniae*.[502] Similarly, on various vegetables[275,276] and on bean sprouts,[358,477] coliforms were predominantly *Klebsiella* spp. *Escherichia coli* is considered as a better indicator of a possible fecal pollution.[216] Most surveys found low numbers of *E. coli*[216,425,426,494] (Table 25-3). Higher levels of contamination with *E. coli* (>10 per g) were found on vegetables imported from tropical countries,[494] on bean sprouts and cress in England[425] and in some samples in Spain.[197] Presence of *E. coli* on raw vegetables was associated with a higher incidence of *Salmonella* in some studies[207,494] but in a survey of over 345 samples in Spain[197] a third of the vegetables positive for *Salmonella* did not contain detectable *E. coli*. In the United States (US), Stewart et al.[487] also failed to find a relation between *Salmonella* and *E. coli* on raw vegetables.

The major agents of foodborne diseases have been detected on vegetables (Table 25-3). Most vegetables were sampled at retail and contamination with pathogenic microorganisms may have occurred after harvest. *Aeromonas hydrophila*[104,248] and the spore formers *Bacillus cereus* and *Clostridium perfringens*[425] were detected in a third or more of raw vegetable samples. The incidence of other pathogenic bacteria on vegetables was lower than 10% in most surveys carried out in developed countries and the bacteria were detected only after enrichment proce-

dures (Table 25-3). However, some publications reported a high incidence of *Listeria monocytogenes* on potatoes and radishes in the US,[231] on bean sprouts in France,[399] and a high incidence of *Salmonella* on lettuce and fennel.[179] In surveys done on various foods, vegetables are usually less contaminated with foodborne pathogens than foods of animal origin[377]: *L. monocytogenes* was not detected in a range of vegetables in Canada[183] whereas it was detected in 26% to 80% of raw meat products. Vegetables may also harbor other microorganisms that are potential pathogens for humans, such as *Pseudomonas aeruginosa*.[218,285,534]

25.2.2 The Effect of Microorganisms on Quality and Safety of Vegetables

Many microbial species cause spoilage of harvested raw vegetables (Table 25-4). In the US, losses due to post-harvest diseases were estimated as 7% to 11% of the crop for tomatoes, 4% for bell peppers, 1% to 3% for potatoes, and 2% to 3% for iceberg let-

Table 25-3 Incidence of Microorganisms of Public Health Significance on Raw, Unprocessed Vegetables

tuce.[230] Occasionally, some microorganisms may be devastating, for example, 60% of a tomato shipment was destroyed by *Mucor mucedo* in the US.[365]

Microorganisms responsible for post-harvest diseases are not necessarily dominant on the surface of sound vegetables: on cabbage leaves *Botrytis cinerea* represented less than 0.1% of the total microflora[202] and on witloof chicory only 3% of the epiphytic isolates caused spoilage upon inoculation.[507] Some spoilage microorganisms may be specific to a few vegetable species whereas others, such as *Botrytis cinerea*, *Sclerotinia* species, *Sclerotium rolfsii*, *Rhizopus stolonifer*, or soft rot bacteria, may attack a wide range of products, the examples given in Table 25-4 are only indicative. The difference between spoilage agents able and those unable to spread during storage (Table 25-4) is of great practical significance. In the first case, losses would increase during the storage period, whereas in the second case, potential losses would be a direct consequence of pre-harvest conditions. The relative importance of spoilage organisms for a given vegetable may differ in different countries and climates. *Mycocentrospora acerina* and *Phythophthora megasperma* were the main cause of spoilage of stored carrots in Normandy, France,[300] whereas in England only *Botrytis cinerea* and *Rhizoctonia carotae* were significant agents of spoilage.[204] In Denmark *R. carotae* was the major cause of post-harvest decay.[257] On freshly harvested cabbage, *Alternaria tenuis* was the main cause of spoilage, *B. cinerea* prevailed on cabbage stored under air, and *Fusarium roseum* was an important cause of spoilage for cabbage stored under modified atmosphere.[3] Some microbial species do not cause spoilage of raw vegetables, but may have an important impact on the quality of processed vegetables. This will be discussed later.

Significant proportions of strains of *Alternaria alternata* and *Fusarium* spp. produce mycotoxins in decaying tomatoes[488] or potatoes.[278,279] Spoiled vegetables would not be consumed directly but traces of spoiled vegetables may be incorporated into processed products. However, a recent report concluded that vegetable products do not represent a significant hazard with regard to mycotoxins in European countries.[464] The situation could be different in de-

Table 25-4 Microorganisms That Cause Post-Harvest Spoilage of Vegetables

These microorganisms cause a large amount of post-harvest spoilage of vegetables, many of them also cause disease or spoilage of vegetables in the field, before harvest. More detailed information is available in references.[151,466]

Microorganisms	*Vegetable*	*Symptoms*	*Mode and Stage of Contamination*	*Reference*
Fungi				
Alternaria alternata and *Alternaria* spp.	Cucurbits Tomatoes, pepper, aubergine Green beans Brassica Potato	Dark lesions	Infection before harvest through injuries, cracks, flower or stem scars, direct penetration of leaves and lenticels	3, 78, 79, 466
Alternaria dauci and A. radicina	Carrot	Black lesions	Infection before harvest from leaves or from injuries of the root	466
Alternaria porri	Onion, leek	Dark rot of bulb	Infection at harvest at the neck site of bulbs or in wounds	466
Ascochyta spp.	Green beans and peas	Dark sunken lesions	Infection in the field through damaged tissue and stem end	466
Aspergillus niger	Onion, garlic	Black mold on the surface of bulbs	Infection via the neck of bulb at harvest through senescent foliage	41, 466
	Yam	Brown firm rot	Infection via wounds at or after harvest	
Botriodiplodia theobromae	Cucurbits Cassava Taro Sweet potato Yam	Wrinkle lesions, soft or dry rot	Wound infection—warm climate	466
Botrytis allii and B. squamosa	Onion	Soft rot	Infection of bulb via the neck through infected leaves	466
Botrytis cinerea	Cucurbits Tomato, pepper, aubergine Green beans and peas Brassica Artichoke Celery Lettuce and chicory Onion, garlic Carrot	Soft rot covered with gray mold	Infection before or after harvest through damaged or senescent tissues, by contact with decaying vegetables; direct penetration of cuticle in the case of "ghost spots" of tomatoes	3, 79, 203, 204, 466, 514
Ceratocystis fimbriata	Sweet potato	Firm rot of dark color	Contamination from infected mother plant and wound infection	466

Table 25-4 Continued

Microorganisms	*Vegetable*	*Symptoms*	*Mode and Stage of Contamination*	*Reference*
Chalara spp.	Carrot	Black patches on the roots	Infection of wounds at harvest	411, 466
Choanephora cucurbitarum	Cucurbits	Soft rot	Infection through decaying flowers—Warm climate	466
Cladosporium spp.	Cucurbits Tomato, pepper, aubergine	Small dark superficial lesions (scab)	Direct penetration or penetration through wounds of injured skin—Mostly initiated before harvest	466
Colletotrichum gloeosporioides, C. coccodes, C. capsici, Colletotrichum spp.	Cucurbits Tomato, pepper, aubergine Green beans Yam	Anthracnose, lesion on the skin	Infection before harvest, direct penetration—Development of decay during maturation of the fruits	79, 217, 334, 352, 466
Colletotrichum circinans	Onion	Smudgy spots on the bulb	Direct penetration of the scale	466
Fusarium oxysporum, F. solani, F. moniliforme, and Fusarium spp.	Cucurbits Tomato, pepper, aubergine Asparagus Onion, garlic Potato Cassava Taro Sweet potato Yam	Lesion covered with white to pinkish mold, dry rot on potatoes, cassava, taros. Symptoms may vary with the species	Infection before harvest from the mother plant or wound infection	3, 41, 79, 466
Geotrichum candidum				
	Cucurbits Tomato Carrot	Soft rot with a sour odor	Wound infection before or after harvest	79, 466
Geotrichum candidum				
	Potato	Brown lesion with a rubbery texture	Infection before harvest of immature tubers	466
Helminthosporium solani				
	Potato	Brown patches on the tubers	Infection before harvest. Dissemination may occur during storage	466
Macrophomina phaseolina				
	Cucurbits	Dry rot, eventually black	Infection by contact with soil—Warm climate	466
Microdochium panattonianum	Potato			
	Lettuce and chicory	Spots and yellow dry lesions	Direct penetration or infection via stomata of leaves before harvest	466

Microorganisms	*Vegetable*	*Symptoms*	*Mode and Stage of Contamination*	*Reference*
Mucor spp.	Aubergine, tomato, pepper	Soft, very wet rot	Infection before harvest, development of decay during storage	79, 365, 418, 466
Mycocentrospora acerina	Celery Carrot	Dark lesions	Contamination in the field, mostly via wounds, but decay development during storage as tissues of vegetables lose their resistance	300, 466
Mycosphaerella brassicola	Brassica	Dark lesions	Direct penetration before harvest and infection through wounds at harvest	466
Myrothecium rodidum	Tomato, pepper, aubergine	Circular, firm, sunken lesions	Wound infection—Decay mostly on ripe fruits	466
Penicillium spp.	Cucurbits Onion, garlic Yam	Lesion or rot covered with blue-green spores	Infection through wounds or injuries, at or after harvest	466
Peronospora parasitica	Brassica	Gray to dark lesions with sparse mold	Infection in the field. Dissemination by contact during storage	466
Phoma spp.	Cucurbits Tomatoes, pepper, aubergine Brassica Celery Potato	Sunken brown to black lesions with black pycnidia, agent of gangrene of potatoes	Infection before or at harvest through wounds, or from infected mother plant	466
Phomopsis spp.	Tomatoes, pepper, aubergine	Sunken brown lesions	Direct penetration (aubergine) or infection of injured tissues before harvest. Soil inoculum	466
Pythium spp.	Cucurbits Green beans and peas Potato Taro	Soft rot	Before harvest, direct penetration by stomatae or injuries from soil inoculum, and infection from the mother plant. Dissemination after harvest by contact with decaying vegetables	466
	Carrot	Cavity spot		466, 220
Phytophthora spp.	Cucurbits Tomato, pepper, aubergine Green beans and peas Asparagus, carrot	Lesions covered with white mold	Direct penetration before harvest from soil inoculum and infection after harvest by contact with decaying vegetables	300, 466

Pseudomonas cepacia, Pseudomonas gladioli pv *alliicola*	Onion, garlic	Soft, slimy rot of bulb scales	Wound infection	315, 466
Pseudomonas viridiflava, P. fluorescens, Xanthomonas campestris, Cytophaga spp.	Cucurbits Tomato, pepper, aubergine Brassicae Asparagus Celery Lettuce and chicory Carrot	Soft rot	Infection via wounds, scars, before or after harvest, and by contact with decaying vegetables. *Xanthomonas campestris* may infect leaves directly before harvest	315, 466
Pseudomonas syringae various pathovars specific for the genus of vegetables	Cucurbits Green beans and peas	Water-soaked spots, which may extend to soft rot	Field disease, but may develop during storage	315, 466

veloping countries if storage facilities and hygienic standards for foods are not adequate.

The presence of pathogenic microorganisms on vegetables can be a cause of human diseases. Vegetables were probably the source of *P. aeruginosa* responsible for infections in hospitals in Brazil: some of the strains isolated from vegetables in hospital kitchens and strains from patients suffering blood, urine, or wound infections had the same serotypes and pyocin types,[138] although cross-contamination of vegetables from the hospital environment cannot be excluded. Vegetables are a minor cause of foodborne incidents of microbial origin, and were incriminated in only 4.8% of cases in Canada from 1975 to 1984,[501] or in only 2% of cases with a known vehicle in the US from 1973 to 1987.[59] However, processed vegetables are the main source of botulism in the US[59] and the number of foodborne diseases associated with fresh fruits and vegetables is increasing.[23] Consumption of contaminated vegetables, either fresh or processed, was suspected to be the origin of cases and outbreaks caused by the main foodborne pathogens (Table 25-5). Vegetables offer, therefore, a sufficient potential for development and survival of foodborne pathogens to transmit human diseases. In some cases, the origin of contamination with the pathogenic organism was traced (Table 25-5), illustrating the need for hygienic practices during cultivation and processing. This is supported by cases of *Salmonella*,[10,123] *E. coli* O157:H7,[70] and virus[415] transmitted by fresh or minimally processed fruits.

25.2.3 Origin of Microorganisms Found on Vegetables

During emergence from the seed, plants become contaminated with large numbers of microorganisms. The first leaves of green endive (*Cichorium endivia*) carried 10^3 cfu cm^{-2}.[369] For sprouts grown in sprouting chambers, the seed is probably the main source of microorganisms. Contamination of sprouts with *B. cereus*[227,403] and *Salmonella* spp.[386,402] caused foodborne disease (Table 25-5), and the bacteria were isolated from the ungerminated seed. On witloof chicory forced under soil cover or under hydroponic systems, part of the microflora of leaves was similar to that of the roots used to grow chicory heads.[507] Seeds are also a source of some post-harvest diseases of vegetables, for example, *Colletotrichum* on pepper.[334] Transmission of post-harvest diseases is more frequent in the case of vegetative seeds, eg, *Botrytis* spp. is the cause of onion bulb neck rot,[344] *Erwinia* spp. is the cause of potato tuber soft rot,[395] and *Phoma* spp. is the cause of gangrene of potato tubers.[310] In such cases, seed transmission is of critical importance because the microorganisms are not common in soil or in the environment.

Some of the predominant microorganisms of vegetables have also been found in the field environment including surface water, irrigation water, soil, and neighboring plants. Contamination with microorganisms from the environment is now recognized as an important feature in the microbial population of cultivated plants.[307] Pectate-degrading bacteria and fluorescent pseudomonads were abundant both on vegetables at harvest and in irrigation water.[382,426] *Rahnella aquatilis*, a member of the Enterobacteriaceae commonly isolated from vegetables, is primarily a bacterium from the aquatic environment.[201] Bacterial spores and resistant forms survive in soil for long periods; the soil is thus a source of contamination for plants with spoilage microorganisms such as soft rot bacilli or clostridia,[315] *Sclerotinia* spp.,[466] *Sclerotium rolfsii*,[409] and *Rhizoctonia solani*.[466] *Sclerotinia* spp.[81,466] attack many weeds, which can be a source of contamination for vegetables. Potential human pathogens such as *P. aeruginosa*, pathogenic bacilli, or clostridia are usually present in soil.[218,289,316,385] *Listeria monocytogenes* was isolated from a significant proportion of samples of soil, water, and plants analyzed in cultivated or uncultivated areas.[133,158,529,530] Thermotolerant *Campylobacter* were isolated from 20% to 55% of samples of river and pond waters in England and North America.[390]

The presence of many foodborne pathogens on vegetables at harvest is frequently assumed to result from a contamination by polluted water or organic fertilizer.[23,98,163,390,425] This is illustrated by a few documented outbreaks of foodborne diseases presented in Table 25-5. *Listeria monocytogenes* was detected in between 100% and 44.6% of samples of sewage or sewage sludge,[8,328,449,523] with numbers up to 50 g^{-1}. Ten percent of samples of alfalfa grown in soil fertilized with sewage sludge cake bore 3 to 5 *L. monocytogenes* g^{-1} at harvest.[8] Wastewater and excreta are widely used in agriculture as a source of fertilizer and irrigation in Asian, African, and Latin American countries,[338] which stresses the importance of this source of contamination.

Domestic animals are a source of bacteria such as *Salmonella*, thermotolerant *Campylobacter*, and *Yersinia* spp., and may also disseminate organisms that cause post-harvest spoilage of vegetables, such as sclerotia of *Sclerotium* spp. and *Sclerotinia* spp., which may be ingested with plant material.[466] Wild

[a] Pathogen and/or toxin detected in the suspected food vehicle.
[b] Toxin production in modified atmosphere packaged cabbage suspected.
[c] Vegetables prepared in hospital kitchen.
[d] Field contamination of cabbage with manure suspected.
[e] Contamination by food handlers suspected.
[f] Contamination by irrigation with untreated wastewater.
[g] Pollution of surface water by septic tanks suspected.
NS = Not stated.

birds may carry *L. monocytogenes*[186] and insects such as *Drosophila melanogaster*, that feed on wounded and decaying fruits and vegetables, can disseminate soft rot *Erwinia* spp.,[315] *Geotrichum candidum*, *Rhizopus* spp., and *Botrytis cinerea*.[103,312]

The presence of microorganisms on harvested vegetables depends on the capacity to survive or to multiply on the plant before harvest. On bean sprouts, the microbial load increased during germination and sprouting from 5–6 log cfu g^{-1} on the seed to 8 log cfu g^{-1},[358,477] but the proportion of enterobacteria increased during sprouting, from less than 0.1% of the total bacteria population in the seeds to 60% in the sprouts. *Bacillus cereus* on bean seeds at 21°C[477] and *Salmonella stanley* on alfalfa seeds at 30°C[255] rapidly multiplied during germination and sprouting, whereas *Staphylococcus* spp. did not multiply and represented a minor part of the microbial population on sprouts.[477] Many post-harvest disease agents colonize the mother plant, produce inoculum, and contaminate the vegetables before harvest (Table 25-4). This is the case with *Botrytis* spp., *Fusarium* spp., and *Sclerotium rolfsii* on various vegetable crops, *Phytophthora* spp. on solanaceous vegetables, *Alternaria* spp. on carrots, and soft rot erwinias on potatoes.[152,466] The plant or its immediate environment may also provide conditions for survival of microorganisms not commonly found in the field. For example, the soft rot bacterium *E. carotovora* survived for a longer period in the rhizosphere of crops than in the soil[315]; pectolytic fluorescent pseudomonads were not found in soil[442] but were abundant in a field where carrots had suffered extensive soft rot[141]; *Listeria monocytogenes* was also suspected to survive better in the rhizosphere of plants than in nonrhizosphere soil.[508] Pathogenic bacteria,[8,170,219,382,432,438,508] viruses,[37,219,288,438,498,521,522] and helminths[431] declined on cultivated plants, but in some studies pathogens survived until harvest.

Numbers of microorganisms may increase during harvesting or handling. The following factors may contribute to this: lack of sanitation facilities for farm workers and poor personal hygiene,[23,207,390] persistence of microorganisms on harvesting equipment,[51,257,473] and multiplication of microorganisms on produce during exposure to warm, moist conditions during harvesting and transport.[455,457] Potato tubers may become contaminated at harvest by *Alternaria alternata* from infected foliage,[168,169] and the use of water to transport potatoes in flumes or for washing may spread contamination with soft rot *Erwinia* spp.[48,53,452] Decaying products in storerooms are another important source of contamination (Table 25-4).

25.2.4 Localization of Microorganisms on Vegetables

On lettuce, chicory, cabbage, or bulbs where leaves are tightly arranged in a head, a decreasing gradient of microbial contamination was observed from outer to inner leaves. Numbers of mesophilic bacteria on outer leaves of lettuces could be 1 to 3 log cycles higher than on inner leaves.[4,280] On white cabbage, leaves are very tightly closed and the number of microorganisms decreased by 4 log cycles from the outer to the central leaves,[281] and only a few microorganisms could be isolated from the core of the cabbage heads.[202] Similar observations were made for witloof chicory[507] and fennel bulbs.[179] On green endive (*Cichorium endivia*), which have looser heads than iceberg lettuce, differences between inner and outer leaves were of 1 log cycle or less.[369] Localization of microorganisms on the surface of vegetables was investigated in a few cases. On green endive leaves[216] and spinach,[35] bacteria were not dispersed over the cuticle, but appeared as microcolonies embedded in a fibrillar matrix, and preferentially located near stomata, in cuticular cracks, or around epidermal hairs, which could be an adaptation of bacteria to the climatic conditions in the field.[157] This is consistent with the observations that bacteria removed from chicory leaf surfaces by a water rinse appeared as microcolonies and not as single cells.[370] However, other observations found individual bacterial cells scattered on the surface of lettuce leaves.[4] On potato tubers, pectolytic *Erwinia* have regularly been isolated from lenticels[210,395] where they survive for longer periods than on the surface of tubers.[315,395] The attachment of phytopathogenic bacteria to plant surfaces was recently reviewed[428] but there is little information on adhesion of saprophytic bacteria on vegetables. Adhesion of conidia of *B. cinerea* to tomato cuticle was recently characterized as a hydrophobic interaction without specific attachment structures, germination increasing adhesion with the secretion of a sheath of base-soluble material.[162]

Fungal agents of storage diseases may have colonized a few cells or a limited area of vegetable tissue at harvest without causing visible spoilage. This is referred to as "quiescent" or "latent infection."[256,408,493] Some fungi such as *B. cinerea*, the cause of ghost spots on tomato fruits, and *Colletotrichum* sp., the agent of anthracnose on pepper, upon contact with the surface of the epidermis may form a specific organ called an appressorium, which permits strong adhesion and penetration of the cuticular layer. More generally, fungi may be present in senescent plant tissues that remain on the vegetable after harvest and trimming, for example, *Sclerotinia* spp., *Botrytis* spp., and *Alternaria* spp. in the basal part of leaves of onion bulbs or of carrot roots, in the calyx of tomatoes, and in the scars left by stem or flowers on many fruit vegetables (Table 25-4). Bacteria, including *Pseudomonas, Xanthomonas, Erwinia,* and, less frequently, *Corynebacteriaceae* have also been isolated from internal tissues of sound cucumber, tomato, green bean, garden pea,[441] potato,[210] and Chinese cabbage.[315] In tomatoes, bacteria were more frequent in the core underlying the stem scar whereas in cucumber they were mostly isolated from the periphery,[441] presumably reflecting a penetration via stem scar or via stomata, respectively. In potato, pectolytic *Erwinia* were isolated from vascular and not from cortical regions of the tubers,[210] presumably transmitted from the rotting mother tubers.

25.3 THE MICROBIOLOGY OF FRESH VEGETABLES DURING STORAGE

25.3.1 Fate of Epiphytic Microorganisms

Numbers of microorganisms on vegetables usually increase during storage, even under refrigeration, which is consistent with the high proportion of psychrotrophs found by many investigators. Aerobic mesophilic bacteria increased from 5.1 log cfu g^{-1} to 6.3 log cfu g^{-1} in 15 days at 2.8°C on iceberg lettuce[280]; from 5.3 log cfu g^{-1} to 7.9 log cfu g^{-1} in 3 weeks at 10°C on white cabbage[281]; from 6.5 to 9 cfu g^{-1} in 6 weeks at 1°C on broccoli[87]; and from 4.8 to 5.8 in 4 weeks at 13°C on tomatoes.[86] At 1° to 2°C, Geeson[202] noted only small changes in the numbers of bacteria, the predominant microorganisms on white cabbage, but found an increase in the numbers of *Botrytis cinerea,* an important spoilage agent of cabbage during storage. Bacterial counts increased only on cabbage drenched with fungicides before storage, presumably because of the presence of free water. All these reports concerned vegetables that did not show visible spoilage.

25.3.2 Development of Microbial Spoilage

Sound vegetables regularly harbor spoilage microorganisms, but infection and development of decay are the results of complex interactions between virulence factors of the spoilage agent and defense mechanisms of the vegetable tissues. The first step is penetration of the vegetable tissues. Upon penetration, microorganisms may invade the host tissues or may be kept in check by the defense mechanisms of the vegetable. In these latter cases the infection is either stopped or the microorganims may remain quiescent until maturation, ageing, or any form of scenescence that reduces the defense mechanisms of the vegetable and permits the development of infection.[256,408,493]

Entry of Microorganisms

The surface of vegetables shows a large diversity in structure and composition; the epidermis is covered by a cuticular layer in aerial organs (leaves, stem, flowers, and fruits) or periderms for roots or tubers. Stomata, lenticels, hair sockets, and scars from detached organs represent natural ways of entry for microorganisms. Cracks in the vegetable surface may occur in certain growing conditions,[174,394] and post-harvest handling may cause injuries and bruising. Some microorganisms can penetrate through the cuticular layer (Table 25-4), eg, *B. cinerea* on tomato fruits,[422,440] *B. cinerea* on cucumber fruits,[178] *Colletotrichum* spp. on tomato and bell pepper,[6,493] and *Colletotrichum circinans* on onion bulbs.[466] Most microorganisms, however, penetrate into vegetables through injured tissues. Spores of *Rhizopus stolonifer* were unable to infect intact tomato fruits[42] but caused a rapid infection on mechanically wounded fruits or on cold-injured fruits. A black rot agent of carrot (*Chalara elegans*) did not cause lesions on unwounded roots,[411] and most pathogens of carrots are unable to penetrate undamaged roots.[303] Under some conditions, scars or lenticels allow invasion of vegetables by soft rot *Erwinia* spp. Hydrostatic pressure caused infiltration of lenticels of potato tubers[53] and infiltration of stem scar tissue of tomato fruits.[48–50] The presence of a film of free water on the surface of potato tubers resulted in bacterial invasion via lenticels and wounds,[320] and infection of inoculated lenticels was observed only when tubers had been incubated at high RH (>80%). Penetration may also occur *via* dead tissues colonized before harvest. *Sclerotium rolfsii* or *Sclerotinia* spp. usually invade the foliage of the carrot plant in the field and then progress to the crown region of the root.[409,466] Similarly *B. cinerea* frequently infects tomato fruits after colonization of the calyx.[152] Fungicide treatment of the calyx reduced incidence of *B. cinerea* and *A. alternata* on eggplant and bell pepper.[181]

Nature of Inoculum

The inoculum of fungal agents of post-harvest diseases of vegetables may be spores or conidia, mycelium, and sclerotia. Mycelium is usually infectious, but spores and sclerotia need to germinate in order to cause infection. Germination of conidia from *Colletotrichum* spp. is influenced by compounds leaching from the surface of the vegetable[493] and by ethylene production.[190] Germination of sclerotia of *Sclerotium rolfsii* and infection of vegetables depend on relative humidity and the presence of certain volatiles.[409] Germination of spores of *Botrytis cinerea* on cabbage leaves from a range of cultivars was positively correlated with the incidence of *Botrytis* rot on cabbage heads during storage.[143] Germination may depend on the availability of nutrients: *Botrytis cinerea,* normally a wound pathogen of carrot, can infect undamaged roots in the presence of nutrients[303]; on onion, conidia of *B. cinerea* suspended in water were unable to cause infection, whereas in the presence of nutrients conidia showed a higher germination rate, longer germ tubes and caused infection[131]; in contrast, conidia of *Botrytis squamosa* on onion were not dependent on nutrients. Mycelium of *Rhizopus stolonifer* was infectious on wounds of sweet potato, but neither dormant spores nor germinated spores were able to invade wounded sweet potato tissues unless macerated sweet potato tissues, and therefore nutrients, were present in the wound.[483] In practical conditions, mycelium produced from infected tissues by some fungi such as *B. cinerea, R. stolonifer, S. rolfsii, Sclerotinia* spp., and *Rhizoctonia carotae* may infect adjacent vegetables during storage, causing a nest of rot and significantly increasing losses during storage (Table 25-4). Although spores of *R. stolonifer* can infect only wounded or injured tomato fruits, undamaged fruits are readily infected by contact with decaying fruits.[42] Senescent leaves on onion bulbs, decaying petioles on carrot roots, or sepals on tomato fruits are important in the infection of vegetables by *B. cinerea* by providing a nutritive base to the fungus.

Virulence Factors of Spoilage Organisms

For microorganisms penetrating directly into the vegetable tissues through the cuticle, production of cutinolytic enzymes[284] is the first step of infection. Among organisms that cause post-harvest diseases of vegetables, *B. cinerea,*[440] *B. squamosa,*[39] *Colletotrichum gloeosporioides,*[284] and *Sclerotium rolfsii*[39] produce cutinase whereas *Rhizopus stolonifer* failed to do so,[378] although the mycelium of the fungus can attack undamaged tomato fruits by contact with infected fruits.[42] Production of biosurfactant was an important factor in the infection of undamaged broccoli heads by pectolytic fluorescent pseudomonads.[233] Pectolytic pseudomonads that did not produce biosurfactants could only infect wounded tissues but could invade undamaged broccoli in the presence of biosurfactant-producing strains. The role of biosurfactant was probably to increase contact between the bacteria and the waxy surface of broccoli.

Many diseases are characterized by maceration of the vegetable tissues (ie, soft rot symptoms) as a result of enzymic degradation of cell wall polysaccharides. Pectin-degrading enzymes[400] play a key role in the development of infection. They are produced early during the germination of fungal spores, and may even be present in the spores before germination.[516] Purified pectin-degrading enzymes were able to cause maceration of vegetable tissues and cell death, without involvement of other enzymes or toxic factors.[55,504] However, microbial pathogens frequently produce several types of pectin-degrading enzymes, which do not always have the same role. Pectin trans-eliminase from *Fusarium oxysporum* f. sp. *cepae* caused maceration of onion bulb whereas the polygalacturonase did not.[238,239] Mutants of the soft rot bacterium *Erwinia chrysanthemi* that did not produce pectin methylesterase or one isoenzyme of pectate lyase had a reduced ability to macerate potato tubers, whereas the other pectate lyase isoenzymes did not seem to be necessary for tissue maceration.[45] The aggressiveness of isolates of *Mycocentrospora acerina* on carrots was related to their production of pectinase and glucanase.[298] In contrast, no production of pectin-degrading enzymes by *C. elegans,* the agent of black rot of carrots, was found.[411]

Oxalic acid is produced by *Sclerotinia* spp.,[330] *Sclerotium rolfsii,*[57,409] *Penicillium oxalicum* on yam,[247] and *Rhizoctonia carotae.*[410] It may contribute to virulence, acting synergistically with pectin-degrading enzymes by sequestering calcium and thereby weakening the middle lamella of the cell wall, or by lowering the pH to a level more favorable to the activity of fungal pectinases. Oxalic acid itself may be toxic to the host tissues and may interfere with the defense mechanisms of the host tissues by inhibiting polyphenol oxidase.[189,330]

Defense Mechanisms of Vegetables

Plant tissues have both preformed barriers against infection and barriers induced in response to infection. Storing vegetables in conditions favorable to the development of such barriers is an important means of reducing decay. Cuticle, epiderm, or periderm tissues are the first preformed barriers against microorganisms. Removing waxes from cuticle increased infection of pepper fruits by *Colletotrichum* *capsici* or *Colletotrichum gloeosporioides*[330] and of cabbage by *B. cinerea*.[448] The lower incidence of *Rhizopus stolonifer* infection on green tomato fruits than on mature ones can be explained by a higher resistance of the epidermis of green fruits. Once injured or wounded, fruits from both stages of development were equally susceptible.[42] The composition of the cell walls may explain in part the resistance of some vegetables. Resistance could be linked to a higher proportion of protopectin (ie, nonsoluble pectin) in the cell wall of carrot,[299] a higher degree of methylation of the pectin,[45,351] or a higher level of calcium in potato tubers.[137,349,350] In these examples, cell walls were presumably more resistant to enzymic degradation. Protein inhibitors of microbial pectinase were detected in tomato fruits[94] and in beet root tissues.[99] The purified inhibitor protected beet root tissues from pectinase of *R. solani* and *Phoma betae* and was in higher concentration in resistant roots.

Resistance of vegetables to infection may be due to preformed antimicrobial compounds. The presence of the phenolic compounds catechol and protocatechuic acid inhibits infection of outer scales of colored onion bulbs by *Colletotrichum circinans*, the agent of smudge disease.[335,466] The periderm and pericyclic tissues of carrot roots, unlike the xylem and to a lesser extent phloem, are very resistant to infection. This was attributed to the high concentration of the polyacetylenic compound falcarindiol.[199] The concentration of falcarindiol in xylem was only 2% of that found in periderm and pericyclic tissues where the concentration (93 $\mu g\ g^{-1}$ fresh weight) was sufficient to inhibit germination of spores of *M. acerina* (ED_{50} of 31.8 $\mu g\ ml^{-1}$). Tomatine could explain the resistance of green tomato fruits to *B. cinerea*, although the fungus can detoxify tomatine.[408,515]

In response to infection by microorganisms, or to various chemical or physical agents (eg, wounds, radiations, heat or cold shocks, ethylene, biotic elicitors), plant tissues may form defensive barriers.[159] These may consist of the synthesis of small molecules, belonging to various chemical groups (phenolics, terpenoids, alkaloids), with antimicrobial properties, named phytoalexins[335] or in the deposition of callose, suberin, or lignin on the cell wall. Phytoalexins play a role in the resistance of freshly harvested carrots[126,214,225] or immature pepper fruit[7] to fungal pathogens. However, accumulation of phytoalexins by potato tubers from different cultivars was not related to resistance to *Erwinia carotovora* var *atroseptica*.[62,63,326] Wounds or infection generally trigger the deposition of lignin on the cell wall or the formation of a suberized layer that can prevent the development of infection,[421] as in the case of potato tuber and soft rot bacteria.[51] In carrot roots, however, wound healing is crucial for resistance to spoilage agents but was attributed more to accumulation of antifungal compounds than to suberization.[200] Other mechanisms involved in resistance of plants, such as lipoxygenase,[461] chitinase,[439] or accumulation of hydroxyproline-rich proteins,[433] are triggered by infection in some vegetables but there is no indication of their role in resistance to spoilage.

In many vegetables the ability to resist spoilage microorganisms decreases during storage. In carrot roots, latent infections with some fungi became progressive after a few months, presumably because of a decline in the ability to accumulate antifungal compounds.[303]

25.3.3 Fate of Foodborne Pathogens

The survival or growth of microorganisms pathogenic to humans on the surface of unprocessed raw vegetables depends on the presence of free moisture, relative humidity, temperature, and exposure to sunlight. Bacteria can grow on vegetables during storage whenever temperatures are favorable (Table 25-6). In some studies, high numbers were reached before the onset of spoilage. Viruses survive for several days on the surface of vegetables under refrigeration and high humidity (Table 25-7), but decline steadily under dry conditions. Microorganisms that are potentially pathogenic to humans and contaminate vegetables during cultivation or at harvest would likely survive, or even increase in numbers, during storage before consumption or processing.

25.4 THE EFFECT OF MINIMAL PROCESSING ON THE MICROBIOLOGY OF VEGETABLES

25.4.1 Treatments Used in Minimal Processing

In this chapter included as minimal processing is any treatment of the vegetables that produces a ready-to-eat or ready-to-use product, but without lethal effect on the vegetable tissues. This excludes heat treatment, freezing, drying, fermentation, or the addition of acid dressings. Minimally processed vegetables are usually trimmed, peeled, cut if necessary, washed, and sometimes disinfected, and frequently packaged in polymeric films. In this latter case, respiration of the vegetable in a sealed package rapidly reduces the concentration of oxygen and increases that of carbon dioxide.[509] The production of minimally processed vegetables started about 30

years ago in the US and was intended mainly for the catering industry. The production has increased rapidly since 1990 because of the development of a retail market.[447] In Europe, production for the retail market started in the early 1980s and grew rapidly. A wide range of vegetables are now minimally processed, including green salads, mushrooms, carrots, celeriac, sprouts, cabbage, onion, broccoli and cauliflower, and vegetable fruits.[12,447]

25.4.2 Microbial Contamination of Minimally Processed Vegetables

Spoilage and Saprophytic Microorganisms

The numbers of microorganisms found on unstored minimally processed vegetables are of the same order of magnitude as those reported for raw vegetables and range from 10^3 cfu g^{-1} on shredded iceberg lettuce to 10^6 cfu g^{-1} on shredded carrots[337] (Table 25-8), with numbers reaching 10^7 cfu g^{-1} for bean sprouts.[510]

The predominant microbial species identified in minimally processed vegetables are those found in whole, unprocessed vegetables.[377] *Pseudomonas, Enterobacter, Erwinia,* and *Rahnella* usually prevail over other genera.[35,47,93,100,116,198,206,280,282,329,336,339,381] Among pseudomonads, most isolates fell into the species *P. fluorescens* and less frequently *P. putida* and *P. chlororaphis.*[254] The most frequently identified Enterobacteriaceae are *Enterobacter agglomerans, Erwinia herbicola,* and *Rahnella aquatilis. Enterobacter intermedium* and *E. cloacae* are less frequently reported. Species of the genus *Serratia, Xanthomonas,* and *Flavobacterium* seem to be less common. Psychrotrophs are an important component of the microflora,[47,198] as discussed for raw vegetables. Populations of pectinolytic microorganisms were determined by various authors as potential spoilage agents, and found to represent 10% to 20% of isolates among mesophilic bacteria from shredded lettuce,[329] or 20% to 60% of fluorescent pseudomonads in many samples of shredded carrots and shredded green endives.[116,381] Populations of pectinolytic bacteria in various mixed salads were estimated as 1% of total mesophilic bacteria.[93] The major pectinolytic species found in minimally processed vegetables[377] were various biovars of *Pseudomonas fluorescens, P. paucimobilis, P. viridi-*

flava, *P. luteola, Xanthomonas maltophilia, Flavobacterium* spp., *Cytophaga* spp., *Vibrio fluvialis*, and some pectinolytic fungi and yeasts (*Mucor* spp., *Sclerotinia* spp., *Trichosporon* spp.). The main difference between the microflora of unprocessed and minimally processed vegetables is the comparatively high proportion of lactic acid bacteria and yeasts found in some minimally processed products (Table 25-8). In some products, atmospheres in packages promoted growth of lactic acid bacteria.[100,115,117] Predominant lactic acid bacteria in minimally processed vegetables were *Leuconostoc* spp.,[100,150,198] and more particularly *L. mesenteroides*,[116] in accordance with the results presented above for unprocessed vegetables. Numbers of yeasts were 3 to 5 log cycles lower than those of mesophilic bacteria for minimally processed lettuce,[280] endive salads,[339] or mixed vegetables for soup,[337] but could reach 10^7–10^8 cfu g^{-1} in shredded carrots.[34] Yeasts identified from minimally processed vegetables fall into many genera, including *Candida, Cryptococcus, Rhodotorula, Trichosporon, Pichia, Torulaspora*, and *Saccharomyces*.[34,280,329,339]

Microorganisms of Public Health Significance

Most of the surveys of foodborne pathogens in minimally processed vegetables (Table 25-9) focused on *L. monocytogenes* because of the general concern about risks of listeriosis with refrigerated ready-to-eat foods and because of the outbreak in Canada linked to the consumption of vegetable mix for coleslaw (Table 25-5).[446] Surveys do not always specify whether products were packaged, and therefore protected from contamination after processing. Products concerned in the studies presented in Table 25-9 were presumably processed in contrasting hygienic conditions, from industries complying with good manufacturing practices to small restaurant kitchens.

In France an incidence of 8.8% was found in 1988,[295] but no positive sample has been reported since 1992 (Table 25-9). In 1996, no *L. monocytogenes* was found in over 605 samples of packaged minimally processed vegetables, whereas the same survey detected 4% to 12% positive samples in other processed vegetables.[399] It is possible that this reduction in contamination for minimally processed vegetables was a result of the application of good manufacturing practices at the end of the 1980s and of the reduction in the number of processors to a few large companies with better hygienic standards. The number of *L. monocytogenes* in positive samples was estimated by the most probable number method to be below 1 g^{-1}.[295] Incidence of *Y. enterocolitica* is usually high (Table 25-9) but all the isolates were considered as nonpathogenic to humans, on the basis of the serotypes and the absence of virulence markers, except in shredded carrots sampled in a restaurant. *Aeromonas hydrophila* was found in a large proportion of samples but it is not known whether these strains had any significance as pathogens. Concern was expressed in the US over the possible development of botulism in products packaged under low oxygen atmosphere,[14] including minimally processed vegetables. In a survey of over 1,118 samples of minimally processed vegetables in the US, *C. botulinum* was isolated from 0.36%.[304] Presence of *Salmonella* spp. and *S. aureus* has not been reported in packaged minimally processed vegetables.

The Effect of Minimal Processing on Numbers of Microorganisms

During minimal processing, the overall contamination of vegetables is reduced by between 1 and 2 log cycles.[198,280,381,502] The removal of the most contaminated part of the vegetables by trimming and peeling (the external leaves of cabbage, lettuces, and green salads, or the periderm of roots) partly accounts for this reduction. The remainder is achieved by the washing procedure, associated in some instances with a chemical disinfection. Nevertheless, some steps in minimal processing could increase the microbial load or could be a source of contamination with foodborne pathogens (Table 25-10).

25.4.3 The Fate of Microorganisms on Minimally Processed Vegetables during Storage

Saprophytic and Spoilage Microorganisms

Packaging and respiration of minimally processed vegetables provide high relative humidity for the growth of microorganisms. However, growth rates are quite variable, even for a single product (Figure 25-1).

In the studies quoted in Figure 25-1, the aerobic mesophilic microflora reached a maximum population of approximately 10^8–10^9 cfu g^{-1} on minimally processed vegetables. Growth rates of lactic acid bacteria and yeasts are more variable than those of aerobic mesophilic bacteria (Figures 25-2 and 25-3) and do not clearly increase with temperature, indicating that growth of these populations may be limited by other factors. High carbon dioxide and low oxygen concentrations in the packages encouraged lactic acid bacteria on shredded carrots,[100,117] on butterhead lettuce,[348] and on shredded endive.[107] The composition of the yeast population of shredded carrots changed during storage[34]: *Cryptococcus albidus*, a nonfermentative species, predominated on unstored carrots and only fermentative *Candida* spp. were isolated after a week at 10°C.

Microorganisms of Public Health Significance

Growth of bacterial foodborne pathogens on minimally processed vegetables is not markedly different from that on raw vegetables (Figures 25-4A and 25-4B). At temperatures between 3° and 10°C, only *L. monocytogenes* and *Aeromonas hydrophila* grew on minimally processed vegetables, with a particularly rapid growth reported for *A. hydrophila*.[31,339] *Escherichia coli, Shigella sonnei*, and *Staphylococcus aureus* survived or decreased in numbers slowly. Above 10°C, most pathogens tested grew, and showed high growth rate as temperature increased, for instance, *S. sonnei* increased 1,000-fold in 12 hours at 22°C on shredded lettuce.[142]

At these temperatures, however, growth may be followed by a rapid death of the pathogen as in the cases of S. *sonnei*[444] and of *L. monocytogenes*[270] on shredded cabbage. *Staphylococcus aureus* is the only bacterial pathogen that showed a poor ability to

grow on most fresh vegetables. However, it grew at 22°C on shredded bell pepper[215] and at 37°C on packaged mushrooms.[97] One hundred *S. aureus* per g produced toxin after 18 hours at 35°C on mushrooms.[340] On minimally processed tomatoes with a pH of 4.1, numbers of *L. monocytogenes* decreased slightly (Figure 25-4C) at 10° and 21°C,[74] whereas *Salmonella montevideo*,[525,542] *Salmonella infantis*, *S. enteridis*, and *S. typhimurium*[30] survived for at least 9 days at 5°C and grew at 20° or 30°C on tomato slices with pH from 3.9 to 4.5. In contrast, *S. montevideo* declined in numbers in the juice of the same tomatoes.[525] The overall measurent of pH presumably did not represent the conditions on tomato slices at the microscopic level.

High storage temperatures permit a rapid growth of bacterial pathogens, but at the same time they accelerate spoilage development and reduce shelf life. Conversely, refrigeration delays spoilage and may increase time for growth of psychrotrophic pathogenic bacteria. Therefore, the important information is the extent of growth or survival of pathogens at time of spoilage development. On shredded green endive, *L. monocytogenes* reached numbers slightly higher at the on-

Table 25-10 Examples of Contamination of Minimally Processed Vegetables of Industrial Origin during Processing

Product	Microorganism	Origin of Contamination	Observation	Reference
Shredded vegetables	Aerobic mesophilic bacteria	Shredders	10- to 100-fold increase of numbers after shredding	198
Shredded lettuce and endive	Aerobic mesophilic bacteria, lactic acid bacteria	Shredders	10- to 100-fold increase of numbers after shredding	259
Sliced carrots	Fecal coliforms	Cutting equipment	10- to 100-fold increase of numbers after cutting	502
Shredded cabbage	*Listeria monocytogenes*	Shredders	Same serotype found on shredders and in the product	295
Various products	*L. monocytogenes*	NS	Incidence higher on processed products than on individual ingredients	90, 513
Shredded iceberg lettuce	*Shigella sonnei*	Food handlers suspected	Outbreaks involving 347 persons traced to shredded lettuce	142

set of spoilage during storage at 10°C and 6°C than at 3°C (Figure 25-5). The bacterium increased in numbers by 100-fold or less before visible spoilage, for storage temperature of 3° to 20°C.[111] However, appreciation of spoilage is subjective. It is difficult to estimate at which spoilage level a product will be rejected by consumers, and therefore to which level of pathogenic bacteria or toxin the consumer might be exposed. For example, respiration of vegetable tissues in packages may create anaerobic conditions and permit toxin production by *C. botulinum* at temperatures of 15°C or above (Table 25-11). Below 15°C, toxin production was usually not observed even with samples inoculated with nonproteolytic *C. botulinum*.[332,396] At temperatures that permitted toxin production, spoilage was observed within a few days, and when toxin was detected, products were considered unfit for consumption in some studies or fit for consumption in others (Table 25-11).

Enteric viruses survived on minimally processed vegetables for several days. From 10^5 pfu g^{-1}, rotavirus inoculated on cut carrots, lettuces, and radishes declined in numbers but were still detectable after 25 to 30 days at 4°C and after 5 to 25 days at room temperature[36]; poliovirus decreased by less than 1 log cycle in 6 to 10 days at 4°C on various cut vegetables and on mixed green salads.[140]

The fate of foodborne pathogenic microorganisms may vary with the vegetable. On minimally processed green salads, *L. monocytogenes* grew faster on butterhead lettuce (*Lactuca sativa*), than on green endive (*Cichorium endivia*), and did not grow on lamb's lettuce (*Valerianella olitoria*).[108] Among a range of shredded vegetables, *S. aureus* grew only on bell pepper.[215] Rotavirus survived for longer periods on lettuce than on radish and carrot.[36]

Other factors may influence growth of a foodborne pathogen on single minimally processed vegetables. The nature of the strains was found important for *C. botulinum*; spores of type A but not of type B strains produced toxin on shredded cabbage.[469] In contrast, the various strains of *L. monocytogenes* tested behaved similarly on minimally processed vegetables.[73,111] *L. monocytogenes* reached higher numbers on minimally processed endive leaves undergoing spoilage, presumably because more nutrients were released.[111] The fate of pathogenic bacteria may also be influenced by amount of inoculum used to measure its growth on minimally processed vegetables. This point is particularly important because most experiments used inoculum levels higher than 10^3 cfu g^{-1}, whereas numbers of pathogens found naturally on vegetables are markedly lower. For example, at 12°C, growth of *E. coli* O157:H7 occurred on various vegetables from an inoculum of 5.0 to 5.3 log cfu g^{-1} but the bacterium declined with an inoculum of 2.2 to 2.5 log cfu g^{-1}.[1] Therefore, results obtained experimentally from

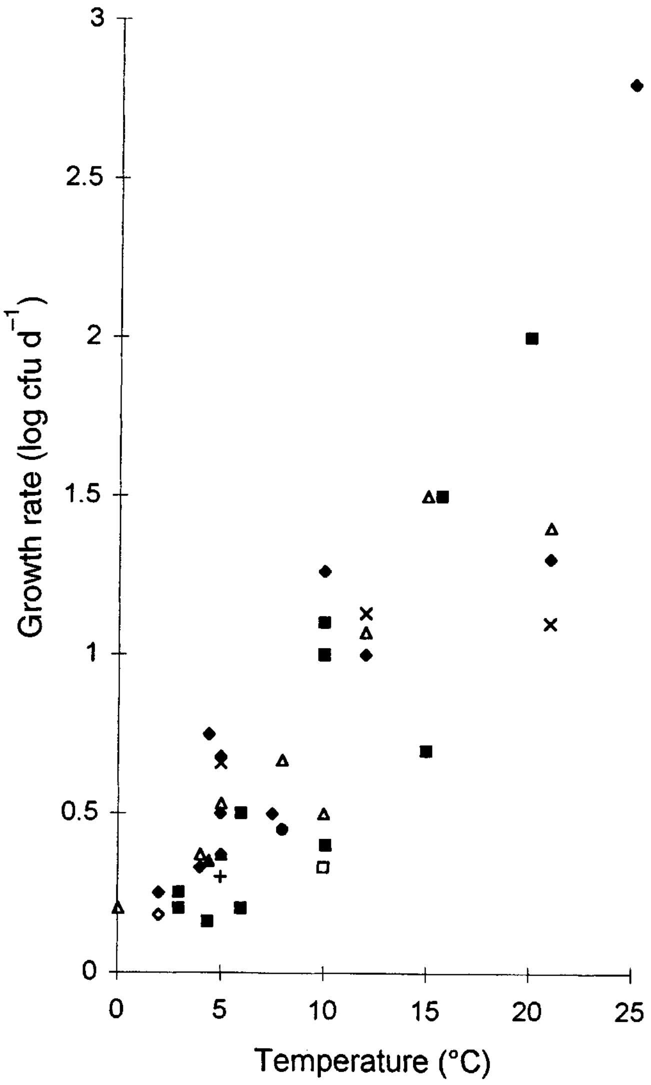

Figure 25-1 Growth Rate of Aerobic Mesophilic Bacteria on Minimally Processed Vegetables As a Function of Storage Temperature. Growth rate was calculated directly, without fitting to a growth model, from the data provided in the references.[1,47,73,74,100,107,111,241,251, 269,280,364,379,405,486,532] Lettuce ◆, endive ■, celery ▲, cucumber ✖, carrots △, broccoli ●, cabbage +, tomato □, onion ◇.

high inocula may not always be extrapolated to the low natural populations. Possible explanations of this are: (1) vegetable surfaces only present a discrete number of sites favorable for growth or survival and low inocula may reduce the probability for the bacteria to colonize these sites, (2) in adverse conditions high numbers of bacteria may create their own favorable environment, or (3) low inocula may fail to compete with other microorganisms.

Growth rate was calculated directly, without fitting to a growth model, from the data provided in the references.[75,107,117,339,379] Endive ■, carrot △, cabbage +, mixed vegetables ✖.

Effect of Processing

Cutting, slicing, or shredding vegetables probably creates favorable conditions for microbial growth. Aerobic mesophilic bacteria grew faster and reached numbers approximately 10-fold higher on cut carrots, cut celery, and shredded lettuce leaves than on the intact vegetables.[280,405] In contrast, Beuchat and Brackett[73] found the same growth of bacteria on shredded and on whole leaves of iceberg lettuce. Wounds may release antimicrobial factors that are not present on the surface of intact vegetables. This is obvious in the case of tomato because the low pH of internal tissues is detrimental to many bacteria. Wounds may also allow contact between enzymes and substrates and thus release antimicrobials.[136,318]

Growth rate was calculated directly, without fitting to a growth model, from the data provided in the references.[34,73,280,339,364,454] Lettuce ◆, endive ■, carrot △, broccoli ●, fennel ○, mixed vegetables ✖.

In *Allium* and *Brassica* spp., enzymatic hydrolysis of sulfur amino acid compounds released antimicrobials: allicin and related compounds in the case of onion and garlic[120] and methyl methanethiosulfinate in the case of cabbage.[128,293,294] Hydrolysis products from glucosinolates[84,506] in brassicas also have antimicrobial properties. However, antimicrobials of this kind have not been found to limit growth of microorganisms in minimally processed vegetables. In shredded carrots, an antimicrobial released by cutting the vegetable tissue inhibited *L. monocytogenes.*[72,379,380] Following inoculation onto shredded carrots the bacterium was killed, and in the presence of oxygen, cut or macerated peeled carrot tissue produced a factor lethal to *Listeria* spp. but not lethal to the indigeneous microflora.

Other responses of plant tissues to processing may influence microbial multiplication. Within a few hours after shredding, carrot tissue reabsorbed the exudate released during shredding.[115] Synthesis of membrane lipids occurred after shredding of carrots, indicating a likely repair mechanism.[398] Shredded carrot also accumulated phenolic compounds, which did not show antimicrobial activities but which are precursors of lignin, in a few hours at 4°C,[33] and lignification of peeled carrot surfaces occurred.[82,240] Both reabsorption of exudate and accumulation of phenolic compounds were inhibited under excessive carbon dioxide concentrations or in the absence of oxygen,[33,115] conditions that also permitted growth of lactic acid bacteria on shredded carrot tissues.[115] These results suggest that wound healing processes may limit microbial development on minimally processed vegetables.

25.4.4 Microbial Spoilage of Minimally Processed Vegetables

Spoilage of minimally processed vegetables is characterized by brown discolorations,[40,83,269,280,348,454] necrosis and soft rot,[381] loss of texture, and production of off-odors.[100,116,269] Spoilage appears during storage as the number of microorganisms increases, but attempts to correlate these phenomena have given conflicting results. High microbial loads on unstored shredded lettuce were related to a short shelf life.[83] For stored samples of shredded endive, there was a negative correlation between total bacterial counts and quality.[235] A threshold of 7.4 log cfu g^{-1} separated well-preserved and spoiled samples. However, the relation between spoilage and microbial counts may vary with storage temperature (Table 25-12), either because different microorganisms became dominant at different temperatures or because other factors participate in spoilage. It may also vary with the kind of vegetables. Batches of shredded broad-leaved endive with a large amount of spoilage contained a higher proportion of pectinolytic fluorescent pseudomonads.[381] In contrast, pectinolytic pseudomonads were present in equal numbers in spoiled and unspoiled samples of shredded carrots and spoilage at 10°C was associated with high numbers of lactic acid bacteria.[116]

Inoculation of 10^7 cfu g^{-1} of some strains of pectinolytic fluorescent pseudomonads caused soft rot on shredded endive within 4 days at 10°C[254,381] and shredded carrots inoculated with *Leuconostoc*

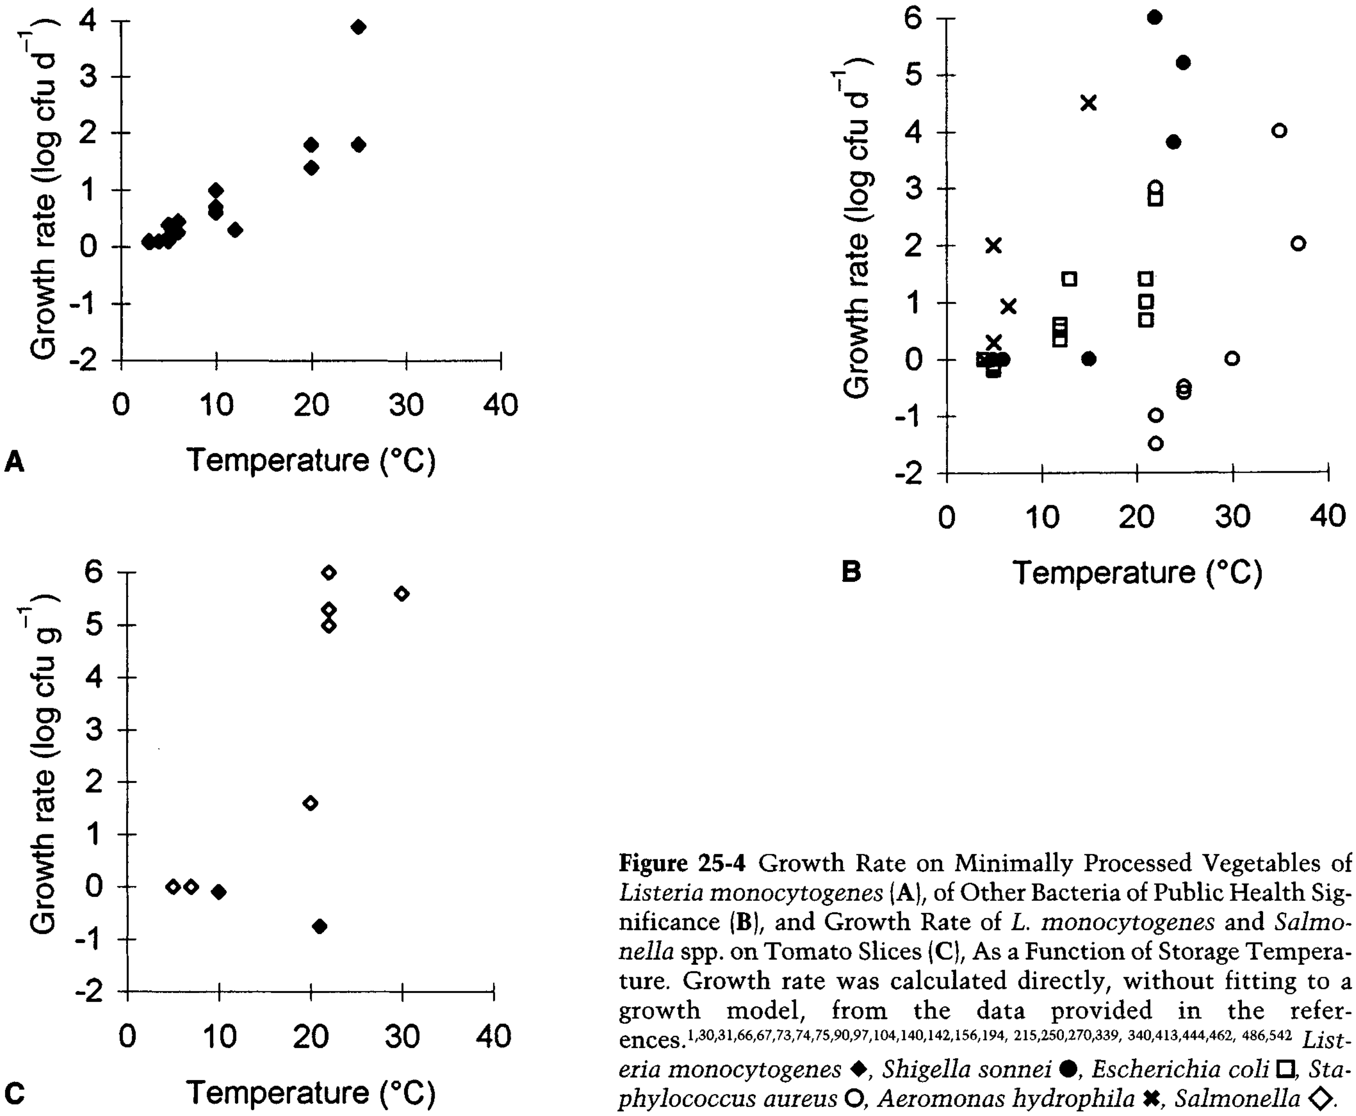

Figure 25-4 Growth Rate on Minimally Processed Vegetables of *Listeria monocytogenes* (**A**), of Other Bacteria of Public Health Significance (**B**), and Growth Rate of *L. monocytogenes* and *Salmonella* spp. on Tomato Slices (**C**), As a Function of Storage Temperature. Growth rate was calculated directly, without fitting to a growth model, from the data provided in the references.[1,30,31,66,67,73,74,75,90,97,104,140,142,156,194, 215,250,270,339, 340,413,444,462, 486,542] *Listeria monocytogenes* ◆, *Shigella sonnei* ●, *Escherichia coli* □, *Staphylococcus aureus* O, *Aeromonas hydrophila* ✖, *Salmonella* ◇.

mesenteroides reproduced the same symptoms as those observed on naturally spoiled samples (ie, exudation and off-odors).[115] However, spoilage on endive leaves inoculated with pectinolytic pseudomonads was reduced under 20% carbon dioxide,[113] and, conversely, *L. mesenteroides* produced symptoms on shredded carrots only under carbon dioxide concentrations above 20% or oxygen concentrations below 2%.[115] Microorganisms may be a cause of spoilage but storage conditions are a determining factor.

Evidence of the role of microorganisms in spoilage of minimally processed vegetables is scant. The reasons may be: (1) cut vegetable tissue can probably withstand multiplication of many microbial species without damage, presumably because of healing processes, (2) minimal processing causes many changes in the vegetable tissue, which may lead to spoilage more rapidly than microorganisms, these changes include increased respiration rate, delocalization of cell compartments, oxidative degradation of substrates, and toxicity of overmodified atmospheres.[509]

Microorganisms causing spoilage of raw, unprocessed vegetables have been isolated from minimally processed vegetables; these microorganisms include *Sclerotinia* spp., *Mucor* spp., and *Pseudomonas viridiflava* in shredded carrots,[116] and pectolytic *Erwinia* in mixed vegetable salads.[93] These microorganisms have never been implicated in spoilage of

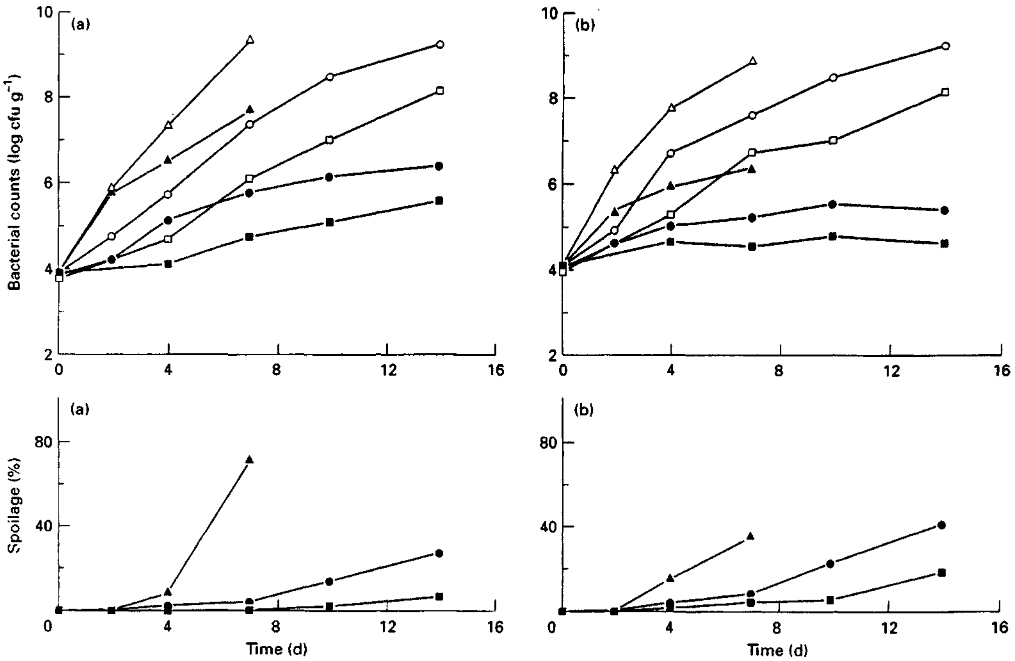

Figure 25-5 The Effects of Storage at 3°C (■, □), 6°C (●, ○), and 10°C (▲, △) on the Population of *Listeria monocytogenes* (closed symbols) and Aerobic Bacteria (open symbols), and on the Extent of Spoilage on Leaves of Shredded Endive at Two Different Times of the Year (a and b). Shredded endive was packaged in a polypropylene film and spoilage was measured by the surface of decay in % of the leaf surface. *Source:* Reprinted with permission from F. Carlin, C. Nguyen-the, and A. Abreu da Silva, Factors Affecting the Growth of *Listeria Monocytogenes* on Minimally Processed Fresh Endive, *Journal of Applied Bacteriology*, Vol. 78, p. 640, © 1995, Society for Applied Microbiology.

minimally processed vegetables, probably because shelf life is too short, compared with the storage of raw vegetables.

25.5 CONTROL OF MICROORGANISMS ON FRESH VEGETABLES

25.5.1 Prevention of Contamination

Polluted water, sewage effluent, manure, or other sources of organic fertilizers are known vectors of microorganisms pathogenic to man or animal, and control of agricultural practices are necessary to prevent contamination. Between 1935 and 1980 in Jerusalem, the incidence of cholera and helminth infections dropped dramatically when supply of vegetables irrigated with polluted water was cut off, and when this practice was eventually stopped.[460] In Peru, cabbage irrigated with polluted water was also a source of cholera.[492] Measures taken to prevent cholera in Chile and in Costa Rica during the 1991–1993 epidemics included destruction of vegetables irrigated with sewage-contaminated water and putting emphasis on wastewater treatments.[343] Health authorities have usually been aware of this risk, and in many places, irrigation of vegetable crops with untreated wastewaters is banned, although enforcement of such measures may be problematic. Wastewater treatments usually reduce numbers of foodborne pathogens.[261] However, in the US, the incidence of rotavirus was similar in raw and treated sewage, whereas the incidence of enterovirus was efficiently reduced.[463] In The Netherlands, *L. monocytogenes* was present in 67% of sewage treatment plant effluents,[158] and in Italy the frequency of *L. monocytogenes* was similar in treated and untreated wastewater, although treatment reduced the number of listeria 100-fold.[65] Microbial pathogens eliminated from sewage would be concentrated in the sludge. For example, *L. monocytogenes*[209,449] and thermotolerant *Campylobacter*[390] are frequent in sewage sludge. However, digestion of sludge may reduce the number of pathogenic microorganisms.[450] Pollu-

tion of surface waters may also be a cause of contamination of vegetable crops. A limit of 1,000 fecal coliform 100 ml^{-1} for irrigation water for vegetables was proposed in the European Union and in the US.[207,261] Disinfection of irrigation waters was also proposed,[261] for instance, by UV treatments,[426] although turbidity of water and fouling may be a problem. Drip irrigation associated with plastic lining of soil also significantly reduced contamination of aerial parts of crops by polluted water[438] compared with spray irrigation. The capacity of some pathogens to survive for several days in cultivated soil, at least 8 weeks for *L. monocytogenes* in soil contaminated with sewage sludge,[523] must be taken into account.[98,390]

Microbial spoilage after harvest frequently results from disease initiated in the field (Section 25.3.2). In such cases, reduction of infection in the field may reduce post-harvest decay. The use of disease-free seeds may reduce post-harvest spoilage. Seed certification schemes exist for *Clavibacter michiganense* on potato tubers.[466] Precautions are necessary to prevent recontamination of the crop by gangrene, silver scurf, skin spot, and blackleg during multiplication of seed potatoes.[310] Dead parts of the plant may be a primary source of inoculum and removal of necrotic tissues on onion leaves in the field reduced significantly both the level of airborne conidia of *Botrytis* spp. and the incidence of the disease.[238] It is frequently advisable to destroy crop debris after harvest to eliminate sources of inoculum for the next crops, for example, to eliminate fungal pathogens of potatoes or carrots.[466] Crop rotation may also help to prevent build-up of inoculum, but this may be hampered by the broad host range of some diseases, which may include weeds, as for *Sclerotinia sclerotiorum*,[81] and by the long survival of some forms of inoculum such as sclerotia of *Rhizoctonia* and *Sclerotinia* spp.[466] or of *Sclerotium rolfsii*.[409] Chemical treatment, solar heat, or microbial antagonist were proposed to reduce sclerotia in the soil.[208,409,466] Reduction of numbers of *Erwinia carotovora* on roots of potato plants, by introducing microbial competitors in the rhizosphzere, reduced incidence of soft rot on stored tubers.[536] Fungicide treatments to protect foliage against *Sclerotinia sclerotiorum* before harvest reduced infection on carrot roots during storage.[406] Such strategies have not always been successful,[434] and the use of fungicides near harvest is strictly regulated. Conditions favoring infection of the plant may be reduced by agricultural practices.[395,409,466] These practices include deep ploughing to bury sclerotia below the layer of soil used by carrot roots; use of cultivars with upright growth to minimize contact of foliage with soil as in the cases of green salads or carrots[406]; protecting foliage from soil by plastic lining and avoiding splashes during irrigation; preventing formation of a humid microclimate by overgrowth of canopy; proper draining of soil to prevent waterlogging;[395] and minimizing mechanical damages at harvest in the case of wound spoilage agents.[168,320]

Prevention of contamination in packing houses, storage facilities, or processing lines relies on a proper cleaning and disinfection of premises and equipment. This is the main objective of the Code of Good Manufacturing Practices for minimally processed fresh vegetables,[24] together with a physical separation of the various steps and a forward progression to avoid cross-contamination of the end-products with wastes or with dirt brought in by raw vegetables.[15] The application of the European Directive 93/43/CEE in European Union member states will lead to regulation of the hygiene of all food products, including storage of raw vegetables. Post-harvest diseases were reduced by disinfection of equipment in contact with vegetables,[51,257] but the main point is disinfection of water used to wash, to cool, or to flume vegetables to avoid build-up of contamination. In carrot packinghouses, 2 to 25 mg l^{-1} chlorine prevented a build-up of *E. carotovora* in the wash water and reduced the incidence of soft rot during storage[452]; similar results were obtained on tomato fruits.[49] Chlorine may be supplied as the gas or as hypochlorite. Its activity is increased at low pH, whereas it is more stable at high pH. A pH between 6 and 7 is an optimum between stability and activity.[319] Fungal propagules need a higher concentration than bacteria to be inactivated, the minimum concentration of free available chlorine reducing the numbers of viable cells by 6 log cycles in 2 minutes at 25°C at pH 6 in water was 0.4 mg l^{-1} for *E. carotovora* and 25 mg l^{-1} for *Geotrichum candidum*.[424] The level of free available chlorine must be monitored and adjusted repeatedly because it combines rapidly with organic material.[51,172,173,315,319] The level of active chlorine is one of the critical points identified in codes of good manufacturing practices for minimally processed vegetables.[24] Alternatively, ozone[482] or chlorine dioxide was proposed[139,416]: concentrations of 0.3 ppm of ozone had a similar effect to 54 ppm chlorine on fungal propagules, and 1.3 ppm of chlorine dioxide was found sufficient to control bacteria in hydrocooling water, whereas higher concentrations produced an excessive odor.

25.5.2 Reduction of Contamination

Destruction of microorganisms that contaminate vegetables relies mostly on chemical treatments, although physical treatments have also been tested. The purposes may be to reduce the general contamination, to remove foodborne pathogens, or to reduce microbial spoilage. Compared with the *in vitro* effect of antimicrobial agents, their use on vegetables is limited by several factors: (1) the microorganisms may not be accessible to the antimicrobial agent, (2) the agent may be phytotoxic, (3) whenever applied as an aqueous solution, free water may remain on the vegetable surface, which may permit spoilage development, and (4) the agent may not be authorized for toxicological or environmental reasons or may not be accepted by consumers.

Water rinsing alone reduces bacterial contamination of vegetables by less than 1 log cycle.[377] It usually has no effect on microbial spoilage,[51] and may even increase contamination or facilitate penetration of microorganisms as discussed above for soft rot *Erwinia* spp. on potatoes or tomatoes. However, washing carrots in water at harvest reduced the incidence of microbial spoilage during storage by a factor of 3 to 5.[309] Among sanitizers, chlorine is widely used, but in spite of its efficiency on microorganisms suspended in water, its effect on the number of microorganisms on vegetables is limited (Table 25-13).[89,377] Sixty percent of the initial level of free available chlorine (100 mg l^{-1}) was found after treatment of lettuce leaves, and microorganisms surviving disinfection were not resistant to the residual level of free available chlorine.[4] The surface-active agent Tween 80 (80 to 100 mg l^{-1}) improved the activity of 100 mg l^{-1} chlorine slightly but caused deterioration of lettuce leaves.[4] Increasing the chlorine concentration above 100 mg l^{-1} and prolonging contact time above 30 minutes did not improve disinfection (Table 25-13). Chlorine concentrations above 300 mg l^{-1} may cause oxidation of equipment and may be an irritant to employees.[4]

Upon reaction with organic matter, chlorine may produce potentially hazardous trihalomethanes. For this reason, and because of a more general concern about the impact of chlorine on the environment, its use for treatment of minimally processed vegetables is banned in several European countries, including Germany, The Netherlands, Switzerland, and Belgium (Assoc. Fr. Fabr. 4ème gamme, pers. comm.). Chlorine dioxide, hydrogen peroxide (Table 25-13), and ozonated water[387] reduced numbers of microorganisms on vegetables but were not more efficient than chlorine.

Microbial populations surviving disinfection grew faster than the corresponding populations on the nondisinfected products, eventually reaching the same numbers, and reduction of numbers of microorganisms by disinfection did not increase shelf life (Table 25-13).[73,112,377,391] The normal saprophytic microflora of endive leaves was antagonistic to *L. monocytogenes*,[112] and *L. monocytogenes* grew faster on endive leaves with an epiphytic population reduced by disinfection.[112] However, disinfection reduced the number of *L. monocytogenes* present on the raw material (Table 25-13). In addition, reduction of numbers of nonpsychrotrophic pathogens by disinfection would persist until consumption if refrigeration during storage is properly maintained. Microbial spoilage of unprocessed vegetables was reduced by some disinfectants (Table 25-14) but concentrations needed were higher than those used to reduce the number of microorganisms (Table 25-13).

Rather than reducing the number of microorganisms, a disinfectant may be more useful in preventing build-up of microorganisms on equipment and in water and to avoid dissemination from contaminated materials. Lower concentrations of disinfectant would probably be sufficient. However, in industrial conditions the large volume of water used to wash vegetables makes on-line control of concentration difficult; it may be advisable to keep the target value higher than the minimum necessary.

Irradiation with doses ranging from 0.5 to 2 kGy had no adverse effect on products stored a few days under refrigeration as minimally processed vegetables.[89,377] At 2 kGy, numbers of bacteria were usually reduced by 3 to 4 log cycles and yeasts by 1 to 2 log cycles. Irradiation seems therefore more efficient than sanitizers. In contrast, most attempts to reduce post-harvest microbial spoilage of raw vegetables failed because the dose required to inactivate spoilage agents, and more particularly fungal propagules, had adverse effects on the product.[346] The shelf life of raw vegetables is longer than that of minimally processed products, which may allow the development of damage induced by irradiation.

Attempts have been made to inactivate microorganisms by mild heat treatment.[43] In aqueous suspension, only 18.3% of spores of *Rhizopus stolonifer* germinated after exposure to 49°C for 2 minutes[465] and 72 hours at 38°C caused a 100% inhibition of *B. cinerea*. This latter treatment inhibited decay on tomatoes treated at the pink stage of maturity, without causing significant modification of the product.[182] However, heat treatments needed to inactivate spoilage agents are very close to the limit of injury to vegetable tissues,[173] and could facilitate attack by microorganisms.

25.5.3 Inhibition of Microorganisms by Chemical and Biological Agents

Post-harvest application of fungicides efficiently reduces spoilage,[153,172] but many spoilage fungi such as *Rhizopus* spp., *Mucor* spp., and *Geotrichum* spp. are resistant to a large number of fungicides.[171,172,365] On carrots post-harvest, benomyl and iprodione dips reduced incidence of *B. cinerea* and *S. sclerotiorum* but failed to control *R. carotae*.[154,204] Resistant strains appear among species normally sensitive,[436] for example, *B. cinerea*[64,308,383,481,520] and potato tuber fungal pathogens.[118] Only a few post-harvest applications of chemicals have been approved by legal authorities, with substantial differences between countries.[2,184]

Natural chemicals have been tested as alternatives to synthetic fungicides. The essential oil carvone in the storage atmosphere reduced decay of potato tubers inoculated with *Phoma exigua* but not with *Fusarium solani*[229]; on bell pepper injured and inoculated with *B. cinerea*, a coating with chitosan reduced decay.[176] Microbial antagonists are another possible alternative (Table 25-15).[167] In the studies on onion, tomato, and cabbage (Table 25-15), antagonists were isolated from the vegetables themselves, indicating that the epiphytic microflora of vegetables could be a natural barrier against microbial spoilage. *Pseudomonas cepacia* mostly acts through the production of the antifungal coumpound pyrrolnitrin.[101] In this case, problems are likely to arise from the appearance of resistant strains among the spoilage microorganisms. The mode of action of other antagonists has not been fully explained. It probably involves competition for nutrients, direct interaction with the pathogen (ie, adhesion to the

[c] Artificial inoculation.

mycelium of the fungal pathogen and destruction), or induction of defense reaction from the host tissues.[166] The efficacy of microbial antagonists could be improved by the addition of nutrients, salts, and the combined application with fungicides. Approval by legal authorities is one major limitation to the use of such antagonists. However, some microbial antagonists have recently been registered for commercial use in the US.[16,166]

For minimally processed fresh vegetables, inoculation of *Lactobacillus casei* reduced multiplication of mesophilic bacteria.[517] The introduction of *L. casei* caused a significant decrease in pH of the product, and unfortunately, the authors gave no indication of the appearance of treated products.

25.5.4 Inhibition of Microorganisms by Control of Storage Conditions

Refrigeration

Refrigeration is widely used for storage of raw vegetables and of minimally processed fresh vegetables.[368] The need for refrigeration during processing of minimally processed vegetables is specified in codes of good manufacturing practice,[24] and refrigeration during transport and retail sale is a legal obligation in France.[15] The rapid multiplication of many foodborne pathogens on minimally processed vegetables at temperatures above 10°C results in the need for refrigeration. Refrigeration of minimally processed endive reduced the growth rate of *L. monocytogenes* more than that of the aerobic microflora,[111] and therefore the assumption that low temperatures may extend the time available for growth of *L. monocytogenes* before microbial spoilage is presumably not true in the case of minimally processed vegetables. Spoilage by some microorganisms may be prevented by storage at low temperatures[153]: eg, soft rot *Erwinia*,[314] *Sclerotium rolfsii*, *Phytophthora* spp., and *Fusarium* spp.[466]; whereas *B. cinerea*,[3,418] *M. acerina*,[300] and *P. fluorescens*[315] cause spoilage of products stored at temperatures close to 0°C.

The efficiency of refrigeration is limited by several factors:

1. Whenever crops of raw vegetables are transferred directly to a cold room, time to reach the target temperatures in the center of the bulk of product may extend to several days, allowing time for nonpsychrotrophs to develop. Two months was necessary to lower the temperature of carrots from 20° to 2°C at the center of 400 kg bins,[503] and 75 days was necessary to lower the temperature to 1°C in storage rooms of carrot.[406] A rapid cooling is frequently advisable before storage; this can be achieved by hydrocooling, forced air cooling, or vacuum cooling.[362] Reducing the time to cool carrots to 1°C from 72 hours to 6 hours reduced the incidence of *S. sclerotiorum* during storage by a factor of 4.[406] For hydrocooling, sanitation of the cooling water must be properly conducted as discussed above.
2. For products that required refrigeration throughout shelf life, such as minimally processed fresh vegetables, temperature fluctuations are liable to occur during transport and retail or in catering facilities.[345,445]
3. Temperatures low enough to restrict growth of spoilage microorganisms cause injury of some crops. Cucumber, tomato, bell pepper, aubergine,

Table 25-15 Examples of Reduction of Post-Harvest Diseases of Vegetables by Microbial Antagonists

Vegetable	*Spoilage Agent*	*Antagonist*	*Effect on Stored Product*	*Reference*
Carrot	*Rhizoctonia carotae, Mycocentrospora acerina*	*Trichoderma harzianum*	Increase of marketable crop by 47% to 75%	503
Onion	*Botrytis allii*	*T. harzianum*	Complete inhibition of spoilage	427
Tomato	*Botrytis cinerea*	*T. harzianum*	Soft rot incidence reduced by 57%	459
Cabbage	*B. cinerea*	*Pseudomonas fluorescens* and *Serratia liquefaciens*	Losses reduced by 50% to 55% (in weight)	301
Potato	*Fusarium sambucinum*	*Pseudomonas cepacia*	Dry rot development reduced by 50% to 90%	101

yam, sweet potato, and many vegetables of tropical origin may develop injuries such as pitting of the epidermis, scald, and necrosis at temperatures below 10°C or even below 15°C. This leads to an increase in microbial spoilage, either by psychrotrophs during cold storage or when the product is brought back to ambient temperature.[134,152,466] Intermittent warming at 20°C during storage of tomatoes at 9°C reduced cold injury, reduced spoilage (caused by *Phytophthora* spp., *Geotrichum* spp., and *Alternaria* spp.) and delayed ageing compared with continuous storage at 9°C, which caused cold injury, or at 12°C, which did not cause cold injury but did not sufficiently delay spoilage and ageing.[28] This method failed to prevent development of injury at 6°C.

4. Traditional cold rooms may cause dehydration of stored vegetables, which may reduce resistance to microbial infection, and therefore increase spoilage. Carrots incubated at 25°C after cold storage developed infection by *R. stolonifer* only if the roots had lost more than 8% of fresh weight during the storage period.[497] Cooling systems maintaining a high humidity are therefore advisable and minimizing weight loss of carrots by high humidity also reduced fungal decay caused by *Sclerotinia* spp.[505] and *B. cinerea*.[204] However, *M. acerina* can cause devastating losses at high humidity[300] and high humidity favored soft rot of carrots caused by *R. carotae*.[154]
5. Temperature fluctuations may cause condensation, which can facilitate penetration by spoilage microorganisms.

Modification of the Storage Atmosphere

The primary effect of the modified atmosphere is usually to reduce the respiration of the produce and therefore to delay physiological changes, which may also reduce microbial spoilage. The modified atmosphere is either actively generated and controlled in the storage room used for raw vegetables (*controlled atmosphere*), or passively generated by the respiration of the vegetables in a sealed package (*modified atmosphere*). In the latter, the composition of the atmosphere tends toward an equlibrium that is a function of the respiration rate, the permeability of the packaging film, and the initial head space of the package.[268] Increasing the storage temperature or stressing the vegetable tissue, as in minimal processing, increases respiration and the extent of atmosphere modification. For a given product, the desired atmosphere composition at equilibrium may be achieved by selection of the packaging film and a given temperature, and by modifying the initial head space of the package.[509] Modified atmosphere packaging was first applied to whole vegetables and later to minimally processed fresh vegetables.[377,509] Atmosphere modifications are limited by the phytotoxicity of carbon dioxide (oxygen) levels above (below) limits that depend on the vegetable and the storage temperature.[249,268,311,509] For long-term storage of raw vegetables, recommended concentrations of carbon dioxide rarely exceed 5% or 10%, and the oxygen level is usually maintained at 3% to 4%, although new techniques permit the use of ultra-low oxygen concentrations, ie, below 1%. In minimally processed vegetables, accumulation of carbon dioxide above 15% or 20%, and a depletion of oxygen below 1% after a few days at temperatures between 5° and 10°C were frequently reported, but this concerns products with short shelf life.[509]

Either oxygen reduction below 5% or increase in carbon dioxide above 10% delays growth *in vitro* of aerobic microorganisms present on vegetables (Table 25-16).[177] No complete inhibition was recorded and atmosphere modification had no remaining effect after transfer of microorganisms to air. Controlled atmosphere reduced microbial spoilage of vegetables like tomato, cabbage, and celery (Table 25-17), although some spoilage agents were not inhibited. Reduction of spoilage may involve mechanisms other than inhibition of growth of spoilage microorganisms. For instance, carbon dioxide inhibited maceration of endive leaves by a culture filtrate of pectolytic *P. fluorescens*.[113,509]

On the contrary, microbial spoilage of potato and carrot was increased, although microorganisms tested were sensitive *in vitro* to atmosphere modifications. Defense mechanisms of the vegetable tissue were probably reduced, as suggested by the greater ability of *E. carotovora* to grow in potato tubers, and by the higher susceptibility of potato tubers to maceration by pectic enzymes of the bacterium, under anaerobiosis.[331] Similarly, atmospheres with increased carbon dioxide or reduced oxygen levels inhibited characteristic reactions of the wound response of carrot tissues, such as accumulation of phenolic compounds and increase in phenyl ammonia lyase activity.[33]

Storage under modified atmosphere packaging reduced microbial spoilage of some raw vegetables (Table 25-18), but, in some cases, the modifications in gas composition were so slight that the positive effect may have been the result of prevention of water loss by the package. Conversely, the high humid-

ity maintained by some packaging material was a cause of increased mold spoilage in packaged tomatoes.[205] On minimally processed vegetables, atmosphere modifications tend to reduce growth of mesophilic bacteria and to increase growth of lactic acid bacteria[336] (Tables 25-17 and 25-18). Spoilage could be reduced by choosing the proper atmosphere composition. This was related to the inhibition of lactic acid bacteria on shredded or sliced carrots, but in other cases the relationship between spoilage reduction and microorganisms was unclear. The fate of foodborne pathogens on raw or minimally processed vegetables was unaffected by atmosphere modifications compatible with maintaining the quality of the product.[1,66,67,73,114,156,270,444]

In the US, modified atmosphere is used in combination with carbon monoxide to improve storage of fruits and vegetables during long distance shipment, with safeguards to prevent harmful effects on employees.[264,265] Carbon monoxide has fungistatic properties, which are enhanced under reduced oxygen concentrations and are more effective than the concentrations in carbon dioxide tolerated by the product.[177,418,420] Carbon monoxide concentrations of 5% to 10% with an oxygen concentration of 4% reduced growth of *B. cinerea* and soft rot of tomato.[267] However, carbon monoxide may hasten ripening of climacteric produce such as tomato.[177]

Anaerobic conditions permit development of strict anaerobes, either agents of spoilage or foodborne pathogens. Pectolytic clostridia caused soft rot of potato tubers in anaerobic conditions.[321] The risk of *Clostridium botulinum* development in minimally processed vegetables raised concern in the US about oxygen depletion in packages of minimally processed vegetables,[14] although the possibility that toxin may be produced before spoilage at temperatures below 10°C seems unlikely (Table 25-11, Section 25.4.3).

25.5.5 Use of the Physiology of Vegetables To Prevent Microbial Spoilage

Procedures based on the defense mechanisms of vegetable tissues have been developed to control microbial spoilage.[471] Some of these procedures rely on accelerating healing of wounds or lenticels by air drying at ambient or moderately high temperatures before storage, as in the cases of potato,[52,54,102] onion,[228,538] carrot,[300] and sweet potato and yam.[466] Fungi like *B. cinerea* frequently attack vegetables after colonization of senescent tissues such as the calyx of vegetable fruits. A treatment with plant growth regulators delayed senescence of aubergine calyx and reduced decay.[495] Selection of adequate practices during cultivation may increase resistance to microbial spoilage: reduction of nitrogen fertilization during production of roots reduced post-harvest bacterial spoilage of witloof chicory[297] and cultural practices may prevent cracking of tomato fruits and post-harvest decay.[394]

Strengthening of the cell walls of vegetables by calcium treatments, either applied directly on the

Shredded carrots	Numbers of aerobic mesophilic bacteria and of *Leuconostoc mesenteroides*	10	21 to 0 : 0 to 40	No effect on total bacterial counts, growth of *L. mesenteroides* and spoilage only for CO_2>20% or O_2<2%	115
Shredded cabbage	Total bacterial counts	5	10 to 2.5 : 0 to 15	No effect on bacterial counts, reduction of spoilage under high CO_2	269

[a]Microorganism inoculated onto produce.

vegetable after harvest or applied as a fertilizer during cultivation in the field efficiently reduced decay of potato tuber by soft rot erwinias.[137,349,350] Extent of decay was negatively correlated with medullar or peel calcium content. Similar effects of calcium were obtained in the case of infection of cucumber fruit by *B. cinerea*.[127] Treatment of minimally processed carrots and courgette with calcium chloride reduced growth of aerobic bacteria.[251–253]

Infection induces defense reactions against spoilage microorganisms. This induction may be systemic as shown for carrot roots in which inoculation with *B. cinerea* and *S. sclerotiorum* near the root tip reduced infection after subsequent inoculation with these fungi near the crown.[354] Various treatments elicited defense reactions and increased resistance of vegetables to a subsequent inoculation with spoilage microorganisms[533]: Ultraviolet C radiation (wave length 180–280 nm) applied to a dose of 10 to 15 × 10^6 erg.cm^{-2} on carrots,[355,356] coating bell pepper with chitosan,[176] and application of glucan from fungal cell walls on bell pepper[7] caused phytoalexin accumulation, ultrastructural modifications, and an increased resistance to the fungal spoilage agent *B. ci-*

nerea. Elicitation of defense reactions in the host tissues was also proposed as one mode of action of microbial antagonists (Section 25.5.3).

25.5.6 Resistant Cultivars

The resistance of vegetables to microbial spoilage differs between cultivars and may depend on susceptibility to penetration by the microorganism and its progression in the vegetable tissues or the production of inoculum (ie, fungal) from the lesion. Such differences have been shown for *Colletotrichum gloeosporioides* on pepper fruits,[333] *Colletotrichum lagenarium* on cucumber,[496] *Botrytis allii* on onion bulb,[306] *Rhizopus* spp. on sweet potatoes,[130] *Pseudomonas fluorescens* on broccoli heads,[106] *Erwinia carotovora* on potato tubers,[296] *E. carotovora* on carrot roots,[357] *Pseudomonas fluorescens* on lettuce,[361] *Phoma* spp. on potato tubers,[310] *Mycocentrospora acerina* on carrot roots,[299] and various spoilage agents on tomatoes.[79] In resistant cultivars, spoilage is usually only delayed and not prevented. Evaluation of resistance of cultivars may depend on testing procedures.[38] The validity of such tests for practical conditions must be considered carefully. Differences in the resistance to spoilage after minimal processing were found between different carrot cultivars,[32] but it is not clear whether they were due to specific traits of some cultivars or the result of growing and storage conditions.

Tomatoes transformed with an antisense polygalacturonase construct were more resistant to postharvest fungal spoilage.[290] The introduction of spontaneous mutation by traditional breeding gave similar resistance but was associated with defects in ripening.[290] The increased resistance of the transgenic tomatoes could reduce the cost of handling, storage, and transportation of vegetables or improve the quality of products with low added value that are not handled with great care, such as vegetables for canning. The defense reaction of vegetables could probably be increased by genetic transformation, but some antimicrobial compounds of vegetables may be detrimental to quality, as in the case of 6-methoxymellein, which causes bitterness of carrots,[472] or may be toxic to humans, as are furanocoumarins in carrot or in celery.[126,155,519]

25.5.7 Microbial Specifications

Microbiological criteria for minimally processed fresh vegetables have been published in European countries such as France, Germany, and the United Kingdom (UK).[319] In France, for example, limits at use-by-date for *Salmonella* (absence in 25 g), *E. coli* g^{-1} ($m = 100$, $M = 1{,}000$, $n = 5$, $c = 2$), and *L. monocytogenes* (100 g^{-1}) are legal standards.[13,15] Limits for aerobic mesophilic microorganisms and limits at production for *E. coli* ($m = 10$, $M = 100$, $n = 5$, $c = 2$) and *L. monocytogenes* (absence in 25 g) are only recommendations for manufacturers.[24] Such criteria are incorporated in codes of good manufacturing practices,[319] and their first purpose is to give indications of any deviations from these practices.[262] Aerobic mesophilic microorganisms are used as an indicator of quality, with the limitations described in Section 25.4.4, and limits have to be adapted to each type of vegetable.[24]

There is no microbial specification for raw vegetables, unless they are incorporated in a processed food, in which case they may have to meet standards defined for this food. Standards and inspection procedures for the quality of raw vegetables exist in several countries[11,266] and include the absence of microbial decay. Attempts have been made to predict the contamination of vegetables with spoilage agents, by methods such as detection of abnormal volatile metabolites produced by infected vegetables[388] or by measurement of incidence of microorganisms on the plant at harvest[232] but the authors of this chapter are not aware of any practical implementation of such measures.

25.6 MICROBIOLOGY OF PROCESSED VEGETABLES

25.6.1 Microbiology of Canned Vegetables

The frequency of contamination of vegetables with spores of *Clostridium botulinum* has been shown to range from 0% to 68% as a result of contamination of the field.[316,385] The minimum heat treatment to achieve commercial safety for foods with pH greater than 4.5 is a 10^{12} kill of *C. botulinum*; ie, a minimum of 3 minutes at 121°C (F_0 3 process). Survival of spores of *Clostridium botulinum* is the result of underprocessing and/or insufficient acidification. Some vegetables with a pH greater than 4.5, such as asparagus, cauliflower, or heart of artichokes are acidified to a pH lower than 4.5 and canned at a lower temperature to keep a firmer texture. Canned vegetables are often highly anaerobic. Oxidation-reduction potentials equivalent to between −440 mV and 0 mV at pH 7 have been reported.[367] The pH of most vegetables is between 4.5 and 7.0, with variations due to growing conditions or cultivars. The pH of tomato, for instance, ranges from 3.2 to 4.9[318]; canning of low-acid tomatoes with an inadequate heat treatment may lead to a botulism hazard.[163] Almost all vegetables at pH greater than 4.5 support growth of, and toxin production by, *C. botulinum.*[109,367,385] Vegetable and vegetable-based foods have been implicated in 24% of the recorded outbreaks of foodborne botulism in the world in the period 1950–1985[385] and in 51% of the outbreaks in the US in the period 1899–1977.[122] Most outbreaks were due to failures in home canning. An F_0 3 process does not totally eliminate other spore formers with heat resistance greater than that of *C. botulinum.* Anaerobic spore-formers that can cause spoilage include *C. sporogenes, C. butyricum, C. pasteurianum,* and thermophilic anaerobes, such as *C. thermosaccharolyticum* and *Desulfotomaculum nigrificans,* mainly in low-acid foods.[316] The aerobes, *Bacillus coagulans* in tomato products and the thermophilic species *B. stearothermophilus* in low-acid vegetables, cause a typical and fairly common spoilage known as flat-sour,[58,191] and have been detected in unprocessed vegetables.[302,539] In practice, therefore, the heat treatment used in canning vegetables to achieve the commercial stability is much greater than an F_0 3 process.[245]

Molds can have an influence on the canning process. Molds growing on fresh or heat-processed tomato can raise the pH (at least locally) to a pH that would allow growth of *C. botulinum.*[79,385] In contrast, vegetable matrices do not seem to markedly influence the heat resistance of bacterial spores during the canning process.[95,96,105,180,188,490]

In conclusion, contamination of canned vegetables with spoilage or pathogenic microorganisms is inevitable. Canning processes are therefore designed to give a 12-D kill of *C. botulinum* and to give commercial stability. Thus, safety and stability of canned vegetables depend quasi-exclusively on the control of the canning process and of the pH of the commodity, the other intrinsic characteristics of vegetables being of negligible significance.

25.6.2 Microbiology of Refrigerated, Processed Vegetables with Extended Shelf Life

Cooked vegetables are frequent ingredients in sous-vide and other refrigerated, processed foods of extended durability (REPFEDs). Cooking results in softening of vegetables.[414] The time to obtain optimal texture and taste ranges from 4 to 13 minutes at 100°C for root vegetables,[222] from 35 to 50 minutes at 90°C, from 4 to 12 minutes at 100°C, and from 3.6 to 4 minutes at 110°C for potatoes.[223,224] The heat treatment required to obtain cooked vegetables with an acceptable sensory quality is not high enough to kill spores of proteolytic strains of *C. botulinum.* That is the reason why REPFEDs must be kept under refrigeration temperatures. Failure in storage at low temperature of ready-to-eat and nonsterile cooked products can result in *C. botulinum* toxin production, as in sous-vide cooked potato[160,325] and has been implicated in numerous serious botulism outbreaks.[18,19,22,327,451]

In contrast to proteolytic *C. botulinum,* psychrotrophic nonproteolytic strains of *C. botulinum* will not survive the cooking process of vegetables because of insufficient heat resistance.[322] However, nonproteolytic *C. botulinum* can survive the pasteurization commonly applied to REPFEDs. In addition, vegetables (mainly brassicae and crucifers) can help heat-treated spores to recover.[489] Many cooked vegetables support growth of, and toxin production by, nonproteolytic *C. botulinum* at refrigeration temperature.[109,110] Time to toxin production is within the range reported for other foods. These are reasons why nonproteolytic *C. botulinum* should be considered as a potential hazard in cooked REPFEDs made of or containing vegetables.

25.6.3 Microbiology of Frozen Vegetables

Prior to freezing, most vegetables (with exceptions such as peppers and leeks) are subjected to a blanching process to inactivate enzymes that can cause deterioration of quality.[531] Blanching consists of exposure to hot water or steam at 90° to 100°C for a few minutes.[187,360,453] Examples of changes in numbers of microorganisms during blanching and freezing processes are shown in Table 25-19.

There are many changes in the numbers of microorganisms in vegetables during processing and freezing (Table 25-19). Washing vegetables has only a slight effect on the microbial contamination. In contrast, blanching has been shown to result in a 100- to 1,000-fold reduction in the microbial population. Procedures performed after blanching (cooling, conveying, packing) tend to increase the microbial load because of contamination from the equipment along the chain. The freezing in itself has generally no significant influence on the microbial population. In general, the numbers of microorganisms in frozen vegetables are stable or decrease slowly during storage at –9°C or –18°C.[360,475,499]

The numbers of microorganisms in frozen vegetables can range from below 10^2 cfu g^{-1} to above 10^7 cfu g^{-1},[44,213,360,423,475] usually from 10^4 to 10^6 cfu g^{-1}. Many different types of microorganisms have been

Table 25-19 Numbers of Microorganisms on Vegetables at Different Stages of the Blanching and Freezing Process

		Microbial Counts (log cfu g^{-1})

isolated from frozen vegetables. These have been listed by Michels[360] and Senter et al.[457] The bacteria are among those found on fresh unprocessed vegetables, eg, *Enterobacter* spp., *Pseudomonas* spp., *Bacillus* spp., micrococci, and lactic acid bacteria. The incidence of yeasts and molds is generally lower than that of bacteria. A major part of the microflora originates from the processing equipment and depends on the hygienic practices used in the industry.

The incidence of *Salmonella* and *Staphylococci* in frozen vegetables is usually low.[44,360,476] *E. coli* was detected in 1% to 36.2% of the packs surveyed[44,213,478]; numbers were generally below 100 g^{-1}. Total coliform and fecal coliform counts gave a poor indication of contamination with *E. coli.*[44,478] *Listeria monocytogenes* was also detected in some frozen vegetables,[213,399] but not in others.[397] The presence of *L. monocytogenes* in frozen foods led to a recall of frozen vegetables.[20] Contamination of frozen vegetables with *L. monocytogenes* is also an indication of poor hygienic practices and/or insufficient blanching treatment. The recommendations on the microbiological limits for frozen vegetables proposed by the International Commission on Microbiological Specifications for Foods (ICMSF)[246] include only a limit on *E. coli*, with $n = 5$, $c = 2$, $m = 100$, and $M = 1{,}000$. The presence of *L. monocytogenes* in frozen vegetables is also undesirable and the French regulation, for instance, includes a limit of $m = M = 100$ *L. monocytogenes* g^{-1}, with $n = 5$ and $c = 2$ for all kinds of frozen vegetables.[21] The ICMSF[246] emphasized the commendable microbiological safety record of prepacked frozen vegetables.

25.6.4 Microbiology of Dehydrated Vegetables

As in freezing, the drying processes for vegetables include grading, washing, and blanching operations. The effects of blanching on vegetables to be dehydrated[359,485,511] are similar to those reported on vegetables to be frozen, ie, a marked reduction in the number of vegetative cells of microorganisms, but a less significant reduction in the number of spore-forming bacteria. In addition, vegetables subjected to drying are also sulfited to prevent browning and discoloration.[524] Despite the known antimicrobial effects of sulfites,[389] there is little information on their actual incidence in dried vegetables. Some vegetables, such as onion or garlic, are not blanched before drying.

Drying of vegetables is usually achieved with hot air. Because of the evaporation of water, the temperature of the product is generally below 50°C, while the temperature of hot air exceeds 80°C.[375] Commodities such as edible mushroom are dried at lower temperatures.[262] In the case of long exposure to drying, microbial growth can occur.[246,375,511] These could be the reasons why microbial counts after drying are not significantly different from those before drying.[359,485]

The number of microorganisms on dehydrated vegetables is very variable. Numbers of mesophilic, aerobic bacteria range from 10 to 10^8 cfu g^{-1}, with most counts between 10^4 and 10^6 cfu g^{-1} (Table 25-20). Numbers of coliforms, yeasts, and molds are also very variable (Table 25-20). The contamination originates from the raw material, from equipment along the processing line, and from storage. The diversity of type and species of bacteria found in dehydrated vegetables is as large as that on fresh unprocessed material (Table 25-21).

Enterobacteriaceae are the most commonly identified contaminants. Pseudomonads, although detected,[237] seem to have a lower incidence than on fresh unprocessed material. Blanching does not eliminate bacterial spores; *Bacillaceae*, thermophilic spore formers,[512] and sulfite-reducing clostridia have therefore been commonly observed (Tables 25-21 and 25-22). Significant counts of molds and yeasts are also reported (Table 25-20). Fungal contaminants are also very diverse and could be also found on unprocessed material (Table 25-21). A mycotoxin-producing *Aspergillus flavus* was detected in sun-dried African vegetables[5]; the authors did not discuss the risk to the consumer. Surveys of dehydrated vegetables for microorganisms of public health significance have shown the relatively low incidence of *S. aureus* and *C. perfringens*. In contrast, 25% of some samples contained *E. coli*, whereas others did not[274,435,458] and 5% of dried asparagus samples were contaminated with more than 100 *E. coli* g^{-1}. Salmonellae were detected in 0% and 23% of the samples analyzed (Table 25-20). The high proportion of positive samples was attributed to East Asian growing practices, including the use of human and animal wastes as fertilizers.[80] Despite this contamination, dehydrated vegetables do not appear to have been implicated in any outbreaks of salmonellosis.[246]

Many guidelines and limits on the level of microbial contamination have been proposed. The ICMSF,[246] for instance, recommends a limit only for *E. coli*, with $n = 5$, $c = 2$, $m = 10^2$, $M = 10^3$, whereas the French committee for the evaluation of the microbial quality of foods requires absence of *Salmonella* in 25 g and recommends *E. coli*, coagulase-positive staphylococci, *B. cereus*, and sulfite-reducing clostridia as indicators of hygienic standards. The proposed limits depend on the product (higher tolerance for mushroom for instance) and on its final use (lower tolerance for ready-to-use dehydrated vegetables such as potato flakes, than for products to be cooked, for instance).[262] Dehydrated vegetables are generally considered as safe, but they are potential sources of spoilage and pathogenic microorganisms when rehydrated or used as ingredients in high water activity food preparations. For example, dehydrated vegetables account for the major part of contamination of dehydrated soups.[273,292] For these reasons, the French legislation, for instance, has authorized the treatment of dehydrated vegetables with ionizing radiation at a maximal dose of 10 kGy to reduce their microbial contamination.[262]

25.7 CONCLUDING REMARKS

The development of minimally processed vegetables highlights microbiological issues linked to fresh vegetables. Elimination of microorganisms is not possible and growth or survival of most microbial pathogens is possible. Such products are therefore not intrinsically safe with regard to foodborne pathogens. Safety relies mostly on prevention of contamination from the field to processing, on a definition of a reasonable use-by date, and on refrigeration. Practices in the field or during harvest may be partly controlled by processors through contracts,

Yeasts and molds	Onion powder and flakes	243	10 to 10^4	372

although this is more difficult for imported vegetables, imports being necessary to provide products all around the year. In contrast, processors have little ability to control refrigeration after processing. This stresses the need for good practices for the purchase of raw material and for processing, and the need for legislation to minimize risks of contamination during cultivation and of temperature abuse during transport and retail. Contamination of vegetables in the field depends on agricultural practices but also on more general environmental issues such as pollution of water resources, and disposal of animal effluents and sewage treatment sludge.

Pressures for practices less damaging to the environment may lead toward a reduction in the use of antimicrobial chemicals in units processing vegetables, or may increase the cost of their use because of the need to treat effluents. Development of organic agriculture may influence the microbiology of vegetables, although heat generated during compost production should inactivate vegetative forms of bacterial pathogens.

The improvement of post-harvest techniques, such as the development of cold storage of some vegetables traditionally kept in the soil over winter, has reduced the incidence of some spoilage microorganisms while it increased others. Agricultural techniques also change dramatically, changing the causes of spoilage. For example, the need to produce tomatoes year round led to the development of glasshouse production, and nowadays in Europe fresh-market tomatoes are seldom grown in fields. Spoilage of tomatoes now depends mostly on the greenhouse microclimate. This situation may be modified again by the development of long-life tomato cultivars that permit long distance shipment at low cost from North African countries. Imports from remote countries may also reduce the need for long-term storage of some vegetables and this will presumably change the nature of microbial spoilage.

Table 25-21 Dominant Microorganisms on Dehydrated Vegetables

Microbial Group	*Dehydrated Vegetable*	*Dominant Organisms*[a]	*Reference*
Bacteria	Range	*Aerobacter, Escherichia, Bacillus, Achromobacter, Pseudomonas, Clostridium, Micrococcus, Lactobacillus, Leuconostoc*	511
Enterobacteriaceae	Range	*Klebsiella/Enterobacter* spp., *Proteus/Providencia* spp., *Citrobacter* spp., *Escherichia* spp.	237
Enterobacteriaceae	Onion	*Enterobacter aerogenes, E. cloacae, Citrobacter* spp.	458
Coliforms	Range	*Aerobacter* spp., *E. coli*	132
Enterococci	Range	*Streptococcus faecium, S. faecalis*	132
Aerobic mesophilic spore-forming bacteria	Onion	*Bacillus subtilis, B. licheniformis, B. cereus, B. pumilus*	458
Molds	African vegetables	*A. niger, A. flavus, A. fumigatus; Rhizopus oryzae, Penicillium oxalicum, Rhizomucor pusillus, Fusarium equiseti*	5
	Mushroom	*Mucor, Rhizopus, Penicillium, Aspergillus*	165

26.1 INTRODUCTION

The fermentation of foods of plant origin is of world economic importance. Fermented food products are made of various raw materials and by using microbial starters dominated by bacteria, yeasts, and/or molds. Several excellent books are available that introduce the reader into the area of fermented foods. These books range from general dictionaries[16,26] to edited volumes dealing with groups of fermented food commodities.[123,132,133,166] Indigenous or traditional fermented foods[152] form the basis of most industrialized food fermentation processes.[151]

This chapter discusses fermented foods made of vegetables, starchy cereals and roots, and proteinaceous seeds. Vegetable fermented foods include cabbages, olives, cucumbers, gherkins, onions, and others, that are preserved by a combination of salt, absence of oxygen, and acidity produced through fermentation mainly by lactic acid bacteria. A minority of yeasts also function in these products; they contribute to the preservation as well as the taste of the products. Certain vegetables, eg, gherkins, are also preserved without fermentation, but through the combination of salt, acid, and chemical preservatives. Some examples of such acidified vegetable products will be included.

Starchy cereals and roots are usually fermented without salt. A variety of processes will be illustrated, ranging from sour maize-based beverages fermented with lactic acid bacteria, to rye- and wheat-based sourdoughs in which yeasts play an essential role, and cassava fermentations aimed at detoxification of naturally occurring cyanogenic glycosides.

Proteinaceous leguminous seeds and oilseeds include peas, soya beans, groundnuts and others. The fermentation of this group of raw materials is targeted toward modification of the major chemical constituent, protein. This is achieved by molds in the preparation of tempe and soya sauce, for example, but proteolytic modification can also take place in bacterial fermentations in which *Bacillus* spp. dominate. Such partially degraded proteins include the much appreciated meat substitutes and condiments (flavorings).

26.2 VEGETABLES AND OLIVES

26.2.1 General Aspects

Range of Plant Materials Used and Products Produced

The traditional preservation of vegetables and oily fruits can be achieved by salting, either by immersing agricultural produce in watery salt solutions (brine), or by mixing fresh produce with crystalline sodium chloride. Because of the osmotic effect of salt, plant juices will ooze out of the vegetables. The nutrients in these juices enable microbial growth. If the storage takes place under anaerobic conditions, the combination of environmental conditions favors the dominance of lactic acid bacteria.[37,40,44,48,99,131,149]

Table 26-1 lists a variety of vegetables and oily fruits (especially olives) that can be fermented this way. The products obtained include sauerkraut, which became popular in the 17th century during long sea voyages, being a shelf-stable, excellent source of vitamin C. A rather similar product is Korean kimchi, obtained by lactic fermentation of salted vegetables, mainly Chinese cabbage, to which a variety of other vegetables, fruits, cereals, and even meat or seafood may be added. Other popular fermented products include pickles (fermented cucumbers) and olives, which are prized as salad ingredients. More recently, a wider variety of vegetables (see Table 26-1), as well as their juices, have been successfully fermented and enjoy increasing popularity as healthy snack and salad ingredients.

In addition to fermentation, a considerable proportion of some of these vegetables, particularly cucumbers, may be preserved by acidifying, salting, and pasteurization so that no fermentation or spoilage takes place, or by acidifying, adding preservatives, and cooling. These acidification procedures lead to a range of less expensive products, with a milder flavor and a more uniform quality.

Range of Types of Fermentation

Table 26-1 shows that lactic acid bacteria are the major fermenting organisms. Heterofermentative, followed by homofermentative lactic acid fermentation, results in both flavor and acidity. A relative minority group are fermentative yeasts. The latter have an important role to play, as scavengers of residual nutrients and oxygen. As a result, potential spoilage-causing microorganisms are inhibited.

Status

Table 26-2 lists some data on the production of fermented olives, cucumbers, and sauerkraut in the two major producing continents. Whereas the olive industry has its center of gravity in Europe (mainly Spain, Turkey, Greece, and Italy),[15] cucumber fermentation industry is mainly concentrated in the United States (US). Sauerkraut production is equally important in Europe (Germany and France) and the US.

Acidified pickles are popular in the United Kingdom (UK), the Netherlands, Germany, and the Scandinavian countries.

Composition of Starting Material

The chemical components found in vegetables used in fermentations, together with the main components of their microbial flora are listed in Table 26-3. Generally, vegetables have a high moisture content, providing a high water activity for microbial growth. Contents of protein, fat, and carbohydrates are relatively low (except for olives with a 20% w/w fat content). The carbohydrates consist mainly of reducing sugars and crude fiber. As the reducing (fermentable) sugars are located within the plant cell structure, they are not available for microorganisms in intact plant tissue. In order to enable fermentation, the cell structure needs to be disrupted, for instance, by mechanical damage as is done while shredding cabbage for sauerkraut. An alternative is to extract the sugars by an osmotic effect, which can be achieved using salt or brine.

26.2.2 Fermentation of Cabbage To Produce Sauerkraut

Method of Production

Sauerkraut (sour cabbage) is shredded and salted white cabbage (*Brassica oleracea*) that has undergone lactic acid fermentation. German food regulations require mininum 0.75% total acidity, pH < 4.1, 0.5%–3% NaCl, and less than 10% of total weight as strainable brine.[67] Special cabbage varieties for fermentation yield large, densely packed heads with a high dry matter content. A flow diagram for sauerkraut production is presented in Figure 26-1.

Green outer leaves and cores are removed and the cabbages are shredded into long strips, 1 to 2 mm wide. The cut cabbage is transported on a conveyor belt into tanks or silos. These may hold between 20 and 100 tons of shredded cabbage. Smaller plastic containers, holding 0.2 to 2 tons are also used. Salt (about 2% by cabbage weight) is added during conveying and filling. Even distribution of salt and controlled filling into containers are important for homogenous fermentation. Brine begins to form as

soon as salt is added, as liquid is extracted from the cabbage by osmotic pressure.

Traditionally, no inoculation of cabbage is carried out. Starting with a well-cleaned silo, the microorganisms that occur naturally on the cabbage will grow and produce a succession of dominant microorganisms.

Silos and vats are covered at the top with a sheet of plastic, the edges of which are draped over the sides to form an open bag. Alternatively, a giant plastic bag with filling hole on top is placed on top of the shredded cabbage. Water, or a brine solution, is then pumped into the bag so that the cabbage is put under slight pressure, which helps to exclude the air, and soon the cut cabbage is immersed in its own brine, without exposure to air. The water used for the closure never comes into contact with the cabbage. In one or more corners of the fermentation silo, a perforated plastic pipe is inserted that reaches the bottom. This pipe allows the escape of gas produced during the first stages of fermentation. The evacuation of gas (CO_2) may also be enhanced by purging, ie, blowing controlled volumes of nitrogen gas or air, from the bottom upwards. The method of flexible sealing

provides optimum fit, in contrast to the ancient method of pressing the cabbage using wooden slats weighted down with stones.

Fermentation may be completed after several weeks at temperatures ranging from 15° to 20°C but may take several months in winter, when the temperature of unheated cabbage may be considerably lower.

The fermented product may be sold fresh from a retail barrel. In this case, the shelf life of the sauerkraut at refrigeration temperatures will be limited to 1 to 2 weeks. Alternatively, for supermarkets, it can be filled in sealed pouches and stored refrigerated. Before filling, the sauerkraut is refermented during an additional period to ensure that all residual sugars have been utilized. This refermentation is initiated by substituting part of the brine by water. These pouches have a shelf life of at least 2 months when stored below 7°C in the dark, or over 3 months when packed with carbon dioxide. If shelf-stable sauerkraut is required, the product must be blanched, canned, and pasteurized.

Microbiological and Chemical Changes during Fermentation

The natural flora of cabbage consists predominantly of strictly aerobic bacteria and some Enterobacteriaceae (Table 26-3). Lactic acid bacteria are always present but usually in numbers not exceeding 1% of total microflora.[44] However, even under conditions of Good Manufacturing Practice, shredder blades and conveyor belts transfer high numbers of lactic acid bacteria to the raw material.

Under conditions of tightly packed shreds, oxygen is rapidly depleted by respiring vegetable tissues and strictly aerobic bacteria.[121] At this stage, there is an increase in Enterobacteriaceae, which produce acids and cause an initial drop of pH to about 4.4 (Figure 26-2).

These Enterobacteriaceae are suppressed within a few days by the acids produced by fast-growing lactic acid bacteria. In this early stage of lactic acid fermentation, heterofermentative lactic acid bacteria, such as *Leuconostoc mesenteroides* and *Lactobacillus brevis,* predominate. Thereafter, homofermentative lactic acid bacteria take over, producing more acid and the pH may drop to 3.7 or lower. Figure 26-3 shows a succession of species that was recorded[119] in sauerkraut with 2.25% salt, fermented at 18°C.

Among the dominant homofermenters, *Lactobacillus plantarum* is a major representative, while *Pediococcus* spp. usually accounts for less than 10%. Other homofermenters, such as *Lactobacillus sake, Lactobacillus curvatus,* and *Lactobacillus bavaricus* have also been recorded, particularly in the early stages of fermentation.[67] Whereas the most spectacular events in microbial succession take place within a week at 18°C, fermentation continues for several weeks thereafter, during which time fermentable sugars are converted mainly to lactic acid and the pH drops steadily to below 3.5.[42]

Controlling factors in sauerkraut fermentation are temperature and salt concentration. At 18°C and 1% salt, heterofermentative lactic acid bacteria are favored, whereas at an impractically high temperature of 32°C and salt concentration of 3.5% homofermentatives are favored.[121] Normal conditions vary between 15°–22°C, with 2% to 3% salt (w/w on cabbage weight), with fermentation periods of 3 to 6 weeks.

The use of starter cultures has been considered, aimed at improving control over the process and the composition of the product. Sauerkraut contains

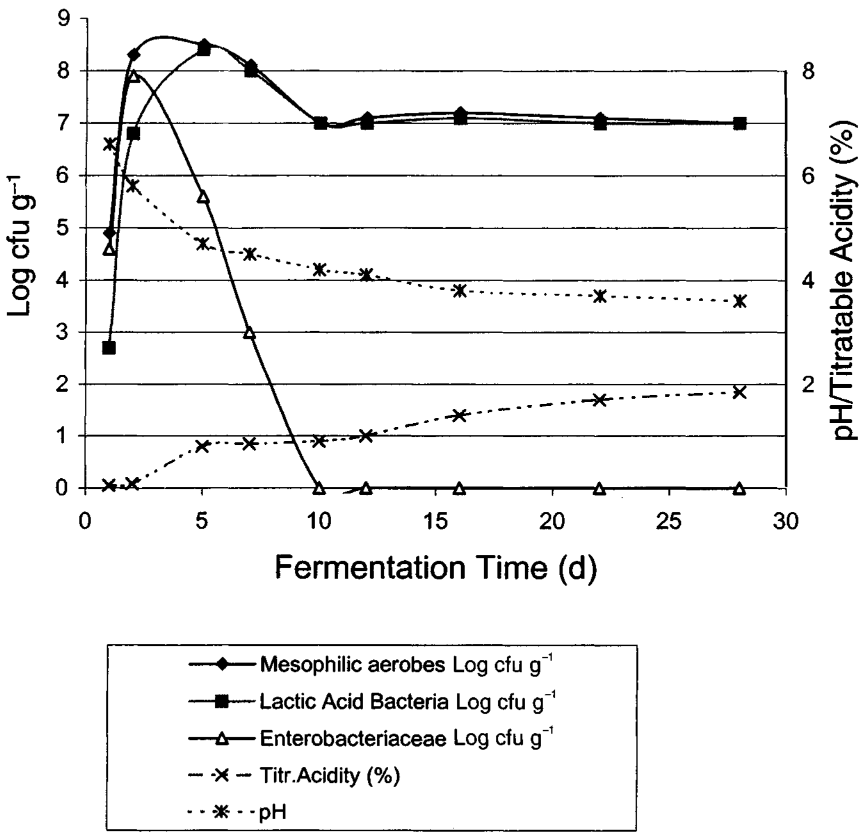

Figure 26-2 Microbiological and Acidity Changes during Sauerkraut Fermentation with 2% w/v NaCl at 18.3°C and Continuous Purging with N_2. *Source:* Reprinted with permission from H.P. Fleming, R.F. McFeeters, and E.G. Humphries, A Fermentor for Study of Sauerkraut Fermentation, *Biotechnology and Bioengineering*, Vol. 31, pp. 189–197, © 1988, John Wiley & Sons Inc.

D(−) and L(+) lactic acid, with an excess of D(−) lactic acid.[67] From a nutritional point of view, it is desirable to have as much L(+) lactic acid as possible, as this can easily be metabolized by the human body. *Lactobacillus bavaricus* produces exclusively the L(+) isomer, and using this organism as a starter culture the sauerkraut contained 70% to 90% of L(+) lactic acid. Addition of a homofermentative starter results in the early suppression of acid-sensitive *Leuconostoc mesenteroides*, which is, however, important for flavor production. Consequently, the product resulting from pure culture *L. bavaricus* inoculation has a rather bland flavor.

Another reason for using starter cultures is to minimize spoilage during storage. This will be discussed in the next section.

Table 26-4 shows the major chemical changes taking place during the fermentation. The data[42] refer to a "nitrogen-purged" sauerkraut fermentation as carried out under controlled conditions. The heterofermentative stage of sauerkraut fermentation is characterized by production of CO_2 (gas), lactic acid, acetic acid, and ethanol. However, because of purging, the CO_2 level was reduced quite soon after it has been produced. Acetylmethylcarbinol (acetoin), diacetyl, and 2,3 butylene glycol are by-products of fermentation that contribute to sauerkraut flavor. In addition, considerable amounts of fructose are reduced to mannitol by the heterofermenters. In Table 26-4 the fructose levels indicate excess sugar that has not (yet) been reduced. Gradually, all sugars that have leaked out of the plant tissue are converted into metabolites. At low pH, esters are formed spontaneously from fermentation products.

White cabbage may contain up to 4.5% w/w (250 mmoles l^{-1}) fermentable sugars, mainly glucose and fructose and some sucrose. These sugars gradually diffuse out of the shreds into the brine and are subsequently fermented. As a consequence the homofermentative stage may last for several weeks or months, during which these sugars are gradually converted to lactic acid (Table 26-4).

Prolonged fermentation can lead to a harshly acidic product, with 2% to 2.5% lactic acid. For this

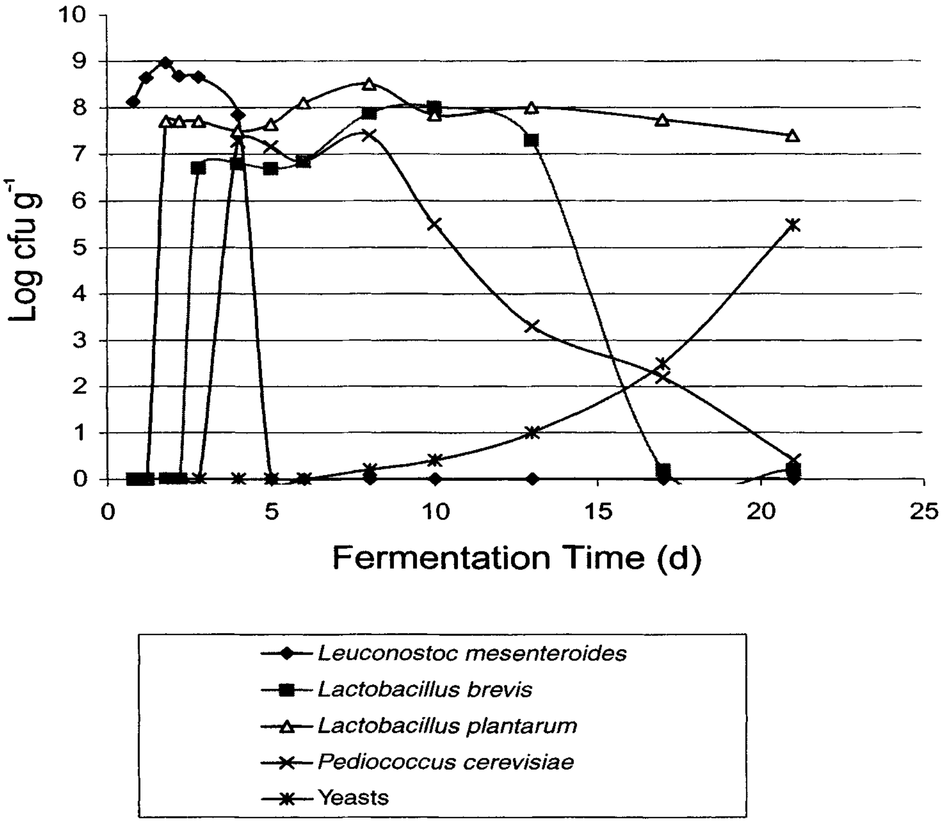

Figure 26-3 Succession of Species during a Sauerkraut Fermentation, with 2.25% w/v NaCl at 18°C. From day 1 to day 21 the pH fell from 4.8 to 3.5 and the titratable acidity increased from 0.15% to 1.78% expressed as lactic acid. *Source:* Data from C.S. Pederson, *Microbiology of Food Fermentations,* © 1971, AVI Publishing Co.

---

reason the fermentation may be interrupted at an earlier stage, eg, when the concentration of lactic acid has reached 0.75%, which is the legal lower limit in Germany. This may be achieved by refrigeration, blanching, and/or pasteurization (see Figure 26-1). The product is then taken out, freshly packaged or canned, and sold as indicated in Figure 26-1.

Prevention of Spoilage

Several sauerkraut defects may be initiated during fermentation. These include:

1. Pink (sometimes gray) discolorations, especially when yeasts (*Saccharomyces exiguus* and pink yeasts) can develop, although *Lactobacillus brevis* has also been incriminated.[150] These form precursors that turn pink or gray when exposed to light and oxygen. A major cause of excessive yeast growth is inadequate acid production by the lactic acid bacteria, as a result of deficiency of manganese,[20] too high salt concentrations, too high temperature, or inadequate exclusion of air during fermentation.
2. Serious flavor defects are produced by butyric acid bacteria that develop and produce butyric acid. This type of spoilage may be because of use of soiled cabbage, irregular salt distribution, or slow development of lactic fermentation.
3. "Soft kraut" often occurs simultaneously with "pink kraut" as it is mainly caused by irregular salt distribution. If in some parts of the silo the salt level is too low, pectolytic enzymes are insufficiently inhibited. These enzymes may be produced by aerobic microflora, if air is inadequately excluded.
4. Slimy sauerkraut may result from polysaccharide (dextran) production by *Leucostoc* spp. when these bacteria grow out massively in fermentations carried out during winter time at unusually low temperatures.
5. Putrefaction occurs if aerobic microorganisms can develop; oxidation of organic acids results

in higher pH values, which in turn enable the growth of microorganisms, eg, pseudomonads.

Spoilage during fermentation may be controlled by adequate homogenous distribution of salt, exclusion of air, and adjusting salt concentration in relation to the temperature.

Exposure to oxygen during retail packaging of fresh sauerkraut should be kept at a minimum. Refermented sauerkraut (see Figure 26-1) is transferred by vacuum suction into plastic pouches, which are heat sealed and must be kept refrigerated (5°C) to avoid overgrowth by yeasts that survive fermentation or contaminate the product during postfermentation handling. Shelf life may be prolonged by adding potassium metabisulfite (if legally permitted), and sodium benzoate (max. 0.1% w/w); a shelf life of 8 to 12 months is feasible.[149] In the Netherlands, chemical preservatives are no longer used in sauerkraut, whereas refermentation is applied frequently.

During bulk storage of sauerkraut, extensive acidification may occur (see Figure 26-2 and Table 26-4). This results from homofermentative fermentation of available carbohydrates. If epiphytic homofermenters could be inhibited, eg, by enhancing heterolactic fermentation by *Leuconostoc mesenteroides,* the kraut would be stabilized. This has been achieved at an experimental scale, using a nisin-producing *Lactococcus lactis* strain,[52] in combination with a nisin-resistant *Leuconostoc mesenteroides.*[53] Nisin-paired starters[13] could suppress epiphytic homofermentative lactic acid bacteria, and postpone homolactic fermentation for at least 20 days, enabling a thorough heterolactic fermentation.

Control of Safety

Botulism arising from improperly canned vegetables has been well-documented.[41] In well-fermented sauerkraut, the combination of 2% NaCl and pH values below 4.5 prevents germination of *Clostridium botulinum* spores and toxin production.[92] However, defective sauerkraut (see above) may not fulfill these requirements, and requires special attention.

Another aspect of toxicity is the production of biogenic amines such as histamine, tyramine, putrescine, and others. In natural (uncontrolled) fermentations, up to 100 ppm histamine was recorded[14] with 200 ppm putrescine. Although these levels are not toxic, a reduction of biogenic amine accumulation could be achieved using selected pure cultures lacking decarboxylase activity.

26.2.3 Fermentation of Cucumbers

Method of Production

Cucumbers for pickling are produced from special varieties of *Cucumis sativis* L. and are harvested at a relatively immature stage, their value being inversely proportional to their size. Pickling cucumbers are preserved by three basic methods: fermentation (curing), pasteurization, and refrigeration. Figure 26-4 shows the principle of the process for fermentation; pasteurized and refrigerated pickles will be mentioned in Section 26.2.5 (acidified products).

Fermentation is the oldest method of cucumber processing. Washed and graded cucumbers are introduced into tanks with a capacity of 2.5 to 25 tons partly filled with a 10% sodium chloride solution (brine), so that during fermentation the concentration of salt may vary between 5% and 8% w/w.

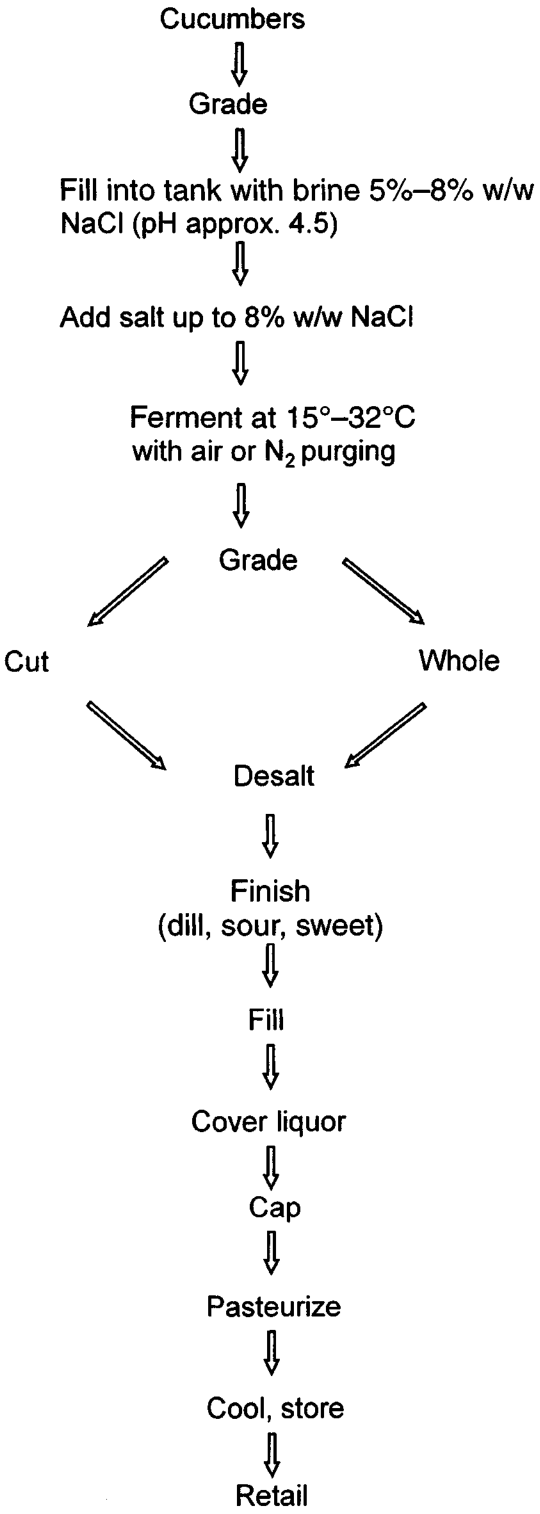
Inoculation is not practiced commercially, but has been investigated at laboratory scale.[120] A microbial succession (see next section) takes place during the fermentation, starting with the microflora present on the cucumbers.[44]

Tanks are covered with headboards or protective plastic covers, such as those used in sauerkraut fermentation. Brines are periodically circulated for mixing. This mixing is also achieved when the tanks are periodically purged with air to remove dissolved CO_2 and prevent bloater formation (cucumbers with gas pockets inside). Originally this purging was done with nitrogen, but this is expensive and it was found that air could also be used. Toward the end of fermentation the salt concentration is gradually increased to between 8% and 16% w/w, so that the pickles may be stored for at least 1 year without spoilage (salt stock or brine stock).

Following fermentation and storage, excessive salt is removed by several changes of water. The pickles are filled into jars or cans, spices and condiments are added, and the product is pasteurized at an internal temperature of 74°C for 15 minutes.

Microbiological and Chemical Changes during Fermentation

A typical example of the succession of groups of microorganisms is shown in Figure 26-5. The rate and extent of growth are influenced strongly by the salt concentration in the brine. Figure 26-5 is relevant for a 40°Salometer brine. 100°Salometer refers to a 100% saturated NaCl solution; consequently, 40°S corresponds with 10.6% w/w NaCl in the brine. Because the initial salt concentration used in pickles is two to three times as high as in sauerkraut,[44] pickle fermentation is more typically dominated by salt-tolerant species. Initially, *Enterobacter* species may multiply and produce acids and gas (carbon dioxide and hydrogen). To prevent excessive gas formation the brine may initially be acidified with acetic acid to pH 4.5.



Cucumbers
Grade
Fill into tank with brine 5%–8% w/w NaCl (pH approx. 4.5)
Add salt up to 8% w/w NaCl
Ferment at 15°–32°C with air or N_2 purging
Grade
Cut
Whole
Desalt
Finish (dill, sour, sweet)
Fill
Cover liquor
Cap
Pasteurize
Cool, store

Table 26-5 lists the major lactic acid bacteria and yeasts found in fermented cucumbers.

Due to its lower salt resistance, *Leuconostoc mesenteroides* is less important in the cucumber fermentation than in the production of sauerkraut. *Lactobacillus plantarum, L. brevis,* and *Pediococcus pentosaceus* are mainly responsible for acid production, and under favorable conditions (5% to 8% w/w NaCl; 21° to 27°C) fermentation is completed within 3 weeks. At higher salt concentrations the rate and extent of lactic acid fermentation are reduced and growth and gas production by yeasts is increased.

Both fermentative and oxidative yeasts have been isolated from brines.[44] The fermentative yeasts have the desirable effect of depleting all residual fermentable carbohydrate matter thus minimizing the growth of spoilage flora. This effect has been shown in a study on mixed *L. plantarum*-yeast (*Saccharomyces cerevisiae* and *Sacch. rosei*) starter cultures.[22] In contrast, oxidative yeasts are regarded as undesirable as they tend to oxidize organic acids and ethanol and to produce off-odors. Oxidative yeasts may be favored if air purging is applied, and fungi may develop and cause softening through their pectic enzymes; potassium sorbate (0.035% w/v) is sometimes added to the brine as an antifungal agent.

Cucumbers contain about 2% glucose and fructose as fermentable sugars which are converted to lactic and acetic acids, ethanol, mannitol, and CO_2. Figure 26-6 summarizes old, but still valuable, data[64] indicating the significant effect of brine concentration. With increasing NaCl concentration, less sugar is converted into acid. This corresponds with increasing gas production by fermentative yeasts that convert the sugar residues during the later stages of the fermentation process. Another fermentable substrate is malic acid (0.2% to 0.3%), which is degraded by *Lactobacillus plantarum* to lactic acid and CO_2. This conversion was discovered when *L. plantarum* was used as a starter and appeared to produce gas in pickle fermentation.[83,84]

Stadler, eds., pp. 629–661, © 1995, VCH Verlag Weinheim.

Prevention of Spoilage

Cucumber fruits may retain their withered flowers, which are laden with pectolytic fungi and yeasts. If these microorganisms are transferred with the fruit into the brine, their pectic enzymes may cause pickle softening.[40] It is important therefore to minimize the introduction of cucumber flowers. Internal softening may also be the result of indigenous polygalacturonase,[44] the concentration of which increases in cucumbers with increase in size and maturity.

Another defect is the formation of bloaters or floaters, resulting from formation of CO_2 by lactic acid bacteria within the cavities. Bacteria, but not yeasts, are able to enter the fruit through stomata.[40] In this case, fermentation gases accumulate in cavities in the central part of larger cucumbers, bringing them to the surface of the brine. This quality defect is avoided by intermittent air purging, to remove dissolved carbon dioxide from the brine. However, purging with air introduces oxygen into the brine, and stimulates development of fungi and oxidative yeasts. As mentioned earlier, nitrogen has been used successfully for purging, but it is too expensive on a commercial scale.

In order to control oxidative fungi including yeasts, acetic acid or calcium acetate and potassium sorbate (less than 0.035%[44]) may be used. Acetic acid is effective against gas-forming enterobacters, fungi, and yeasts, whereas calcium ions act as firming agent on cucumber tissue by binding to pectic substances. Oxidative yeasts may also proliferate on the surface of brines in poorly covered tanks. These yeasts utilize lactic acid causing the pH to rise and thus allowing spoilage bacteria to grow. Butyric acid fermentation, resulting in offensive odors, may be initiated in brines with very low salt concentration, but this would be indicative of a gross processing failure.[43,44]

26.2.4 Fermentation of Olives

Method of Production

In 1991 and 1992 world production of table olives had reached 893,000 tons (Table 26-2), with the main production countries as follows: Spain (227,000 tons), Turkey (110,000 tons), Italy (100,000 tons), Morocco (85,000 tons), and Greece (80,000 tons).[48] Table olives are fruits of specific varieties of the cultivated olive tree (*Olea europaea sativa* Hoffmann et Link). They are harvested at various stages of ripeness (from green to black) and processed in different ways, to remove the natural bitterness caused by the glucoside oleuropein, and improve their organoleptic characteristics.[37]

Olives are fleshy stonefruits, the pulp accounting for 70% to 90% of the weight and the stone (endocarp) for 10% to 30%. The lipid content varies between 6%

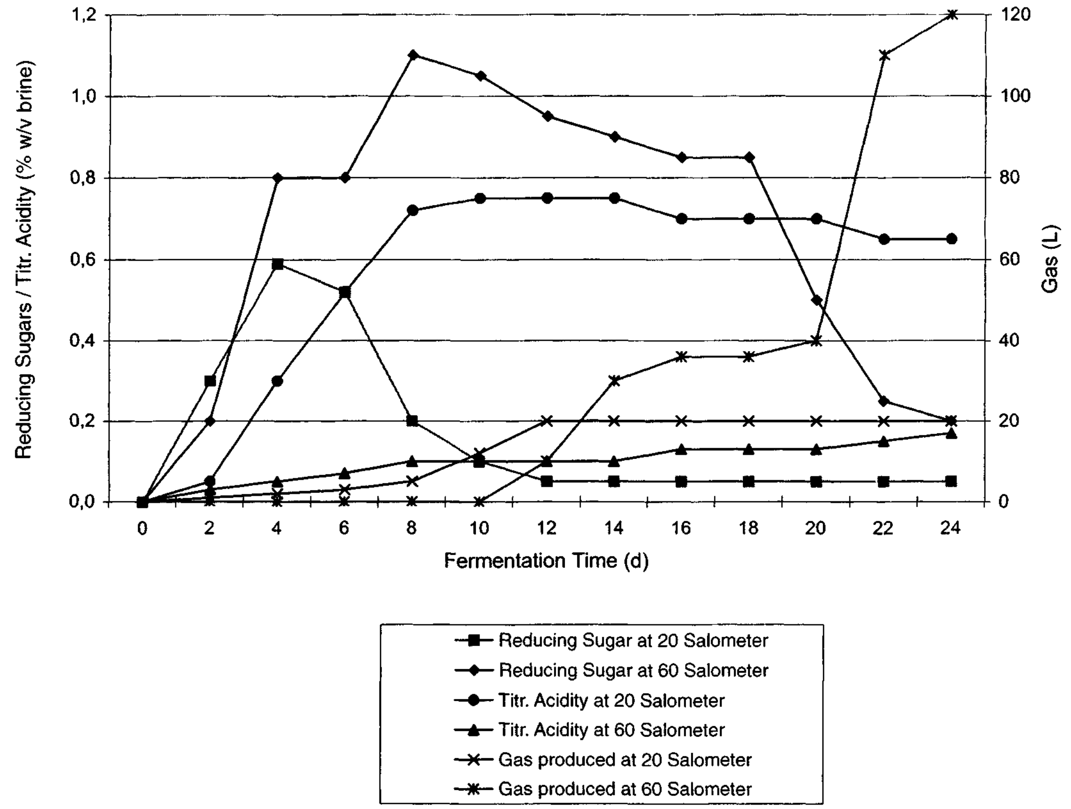

Figure 26-6 Chemical Changes Occurring during Cucumber Fermentation, As a Function of Brine Concentrations (20° and 60° Salometer, Corresponding with 5.3% and 15.9% w/w NaCl, Respectively). *Source:* Data from I.D. Jones and J.L. Etchells, Physical and Chemical Changes in Cucumber Fermentations, *Food Industry,* Vol. 15, pp. 62–64, © 1943.

and 30%. Fermentable sugars are glucose (1% to 3% of flesh), fructose (0.1% to 1.1%), and small amounts of sucrose and mannitol. Citric, oxalic, and malic acids are present in a total concentration of 0.5% to 1.0% of the weight of the flesh. This also contains 1% to 3% of phenolic compounds, mostly *ortho*-diphenols and their glucosides, which play an important role in fermentation because of their antimicrobial properties, specifically against lactic acid bacteria. The phenolic compounds are also important in the color development during ripening and in the darkening process for preparing ripe olives in brine.

The three major preparation methods for table olives are shown in Figure 26-7; major processing stages are summarized in Table 26-6.

In commercial production, olives are not inoculated with starter cultures. The processes rely on combinations of environmental factors (eg, salt, temperature, presence of microorganisms on fresh olives, and microflora attached on equipment).

For "treated green olives in brine"[48] the olives are picked when they have reached a green to straw-yellow color. They are treated in cylindrical or spherical polyester and glass fiber tanks with 1.3% to 2.6% w/v lye solution (NaOH) for 5 to 7 hours to hydrolyze oleuropein. The lye solution is then drained away and the olives are washed repeatedly with water, which removes some of the oleuropein and its hydrolysis products, other polyphenols, and some of the fermentable sugars. The olives are then put in brine containing 5% to 6% w/v NaCl to allow fermentation, which is mainly by lactic acid bacteria. The olives may be kept in the same brine until further processed, and sold after increasing the salt concentration to 8% w/v. These green olives, when fermented completely, are known as "Spanish-style green olives."

"Untreated natural black olives in brine" are prepared from violet to black olives. These are immediately brined (usually the brine has 8% to 10% w/v NaCl concentration initially) and fermented, predominantly by yeasts.

"Treated black olives in brine" (ripe olives) are prepared from olives, picked at various stages of ripeness, from yellowish-green to purple. They are usually stored in brine (5% to 7% w/v NaCl initially) prior to the oxidation (blackening) process, carried out with 1% to 2% w/v sodium hydroxide solutions and purging with air. After final washing, their pH may vary between 5.8 and 7.9. The black color is stabilized by adding iron salts. The olives are canned in a 2.5% to 5% w/v brine solution and sterilized.

Microbiological and Chemical Changes during Fermentation

"Treated green olives in brine" undergo the most extensive fermentation, in which lactic acid bacteria play a dominant role (Table 26-6 and Figure 26-8). Following lye treatment and washing, the olives are brined so that the final NaCl concentration is 5% to 6% w/v of brine during fermentation. In the first stage of fermentation (2 to 3 days) Gram-negative rods, Enterobacteriaceae (coliforms), and *Bacillus* spp. predominate. These are contaminants from olives, tanks, and washing waters. As a result the pH decreases from an initial value of 8.0 or higher, to 6.0 or below. In this stage gas formation (CO_2, H_2) is due to Enterobacteriaceae and *Aeromonas* spp. As fermentation progresses, *Pediococcus* and *Leuconostoc* spp. appear and a second stage of fermentation sets in, in which *Lactobacillus plantarum,* and to a lesser extent *Lactobacillus delbrückii,* take over. Figure 26-8[47] illustrates quantitative changes in predominant microorganisms, in combination with some chemical changes. During the second stage of fermentation (12 to 15 days), the pH should ideally drop to below 4.0. This pH drop depends on the concentration of fermentable sugars present and the buffering capacity due to salts of organic acids from olives, formed during treatment (so-called combined acidity or residual lye). Interestingly, unlike in sauerkraut and cucumber fermentation, in this type of olive fermentation pediococci may appear first, before leuconostocs and lactobacilli. This phenomenon may be due to the salt concentration and/or the resistance to polyphenols. During the third stage of fermentation, which lasts until substrates are exhausted, species of *Lactobacillus,* mainly *L. plantarum,* predominate and these coexist with a yeast flora.[38] *L. plantarum* requires vitamins and amino acids for its growth, and some of the yeasts appear to release B-vitamins.[134,135] The fermentative yeasts use a certain proportion of fermentable sugars, but their metabolites, such as ethanol, ethylacetate, and acetaldehyde contribute to the organoleptic characteristics of the product. Oxidative yeasts may occur also in superficial films. They should be kept low by anaerobiosis, as they oxidize lactic acid, raise the pH, and thereby may favor malodorous spoilage by *Clostridium* spp. Suppression of oxidative yeasts can be achieved by covering brine surfaces with plastic films. At the end of fermentation, the salt concentration is raised to 8% w/v to suppress possible development of *Propionibacterium,* which may cause an increase in pH and induce malodorous spoilage.

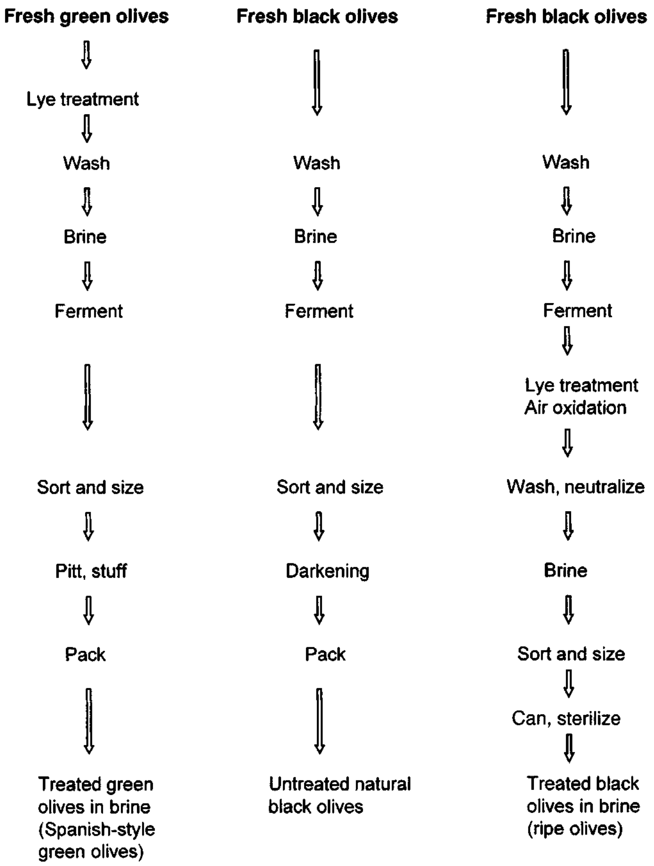

Figure 26-7 Three Methods of Olive Processing. *Source:* Adapted with permission from A. Garrido Fermandez, P.G. Garcia, and M.B. Balbuena, Olive Fermentations, in *Biotechnology, Vol. 9, Enzymes, Biomass, Food and Feed.* H.J. Rehm, G. Reed, A. Puhler, and P. Stadler, eds., pp. 593–627, © 1995, VCH Verlag.

"Untreated natural black olives in brine" are put immediately in brine of 8% to 10% salt (Table 26-6). The fermentation process is slow, as diffusion of soluble compounds through the skin of the fruits is slow when no lye treatment has been applied. Gram-negative bacteria are present in the first few days but disappear after 1 or 2 weeks. This fermentation is dominated by yeasts, which reach maximum num-

bers after 10 to 25 days. The rather high salt concentration compared with treated green olives in brine, is an important factor in the yeast dominance. Fermentative yeasts, such as *Saccharomyces oleaginosus* and *Hansenula anomala* are always found, along with some facultative oxidative yeasts, such as *Torulopsis candida, Debaryomyces hansenii, Candida diddensii,* and the oxidative species *Pichia membranaefaciens.*[79] However, *Pediococcus* and *Leuconostoc,* and in a later stage *Lactobacillus* species, also occur and produce acids. The major fermentation products are lactic and acetic acids, ethanol, ethylacetate, acetaldehyde, acetone, n-propanol, 2-methyl-propanol, and 2-methyl butanol. In this type of fermentation, air purging may be applied to remove excessive CO_2 and prevent gas pocket spoilage and shrivelling of fruits. As a consequence, the dissolved oxygen concentration is higher in this fermentation than in treated green olives in brine, and this favors growth of oxidative yeasts. The final pH is between 4.3 and 4.5, while the acid concentration varies between 0.3% and 0.5%. For this reason, at the end of fermentation the salt concentration should be raised to 8% to 10% to ensure adequate preservation.

"Treated black olives in brine" (ripe olives) typically undergo an alkaline oxidation process to achieve complete blackening of the fruit skin and uniform dark coloration of the pulp (Table 26-6). This oxidation process may be applied immediately after harvest, or the fruits may be stored in brine and fermented prior to oxidation. During storage in brine, air injection may also be applied with these olives to enhance the oxidation (blackening). Depending on varietal differences in phenol levels and salt concentration in the brine, either yeasts or lactic acid bacteria may dominate the fermentation. Induced lactic acid fermentation resulted in adequate preservation prior to oxidation treatment.[28] In order to cause blackening, fruits are repeatedly treated with sodium hydroxide solutions (1% to 2%) and water in which air is injected under pressure; usually this is achieved in three to five successive treatments. The alkaline oxidation of phenolic compounds causes a complete blackening of the fruit skin and a uniform darkening of the pulp. During finishing, most of the sodium hydroxide is removed; this is ensured by washing until the pH of the flesh is approximately 8. Finally, the olives are canned or bottled in a brine of 1.5% salt and sterilized.

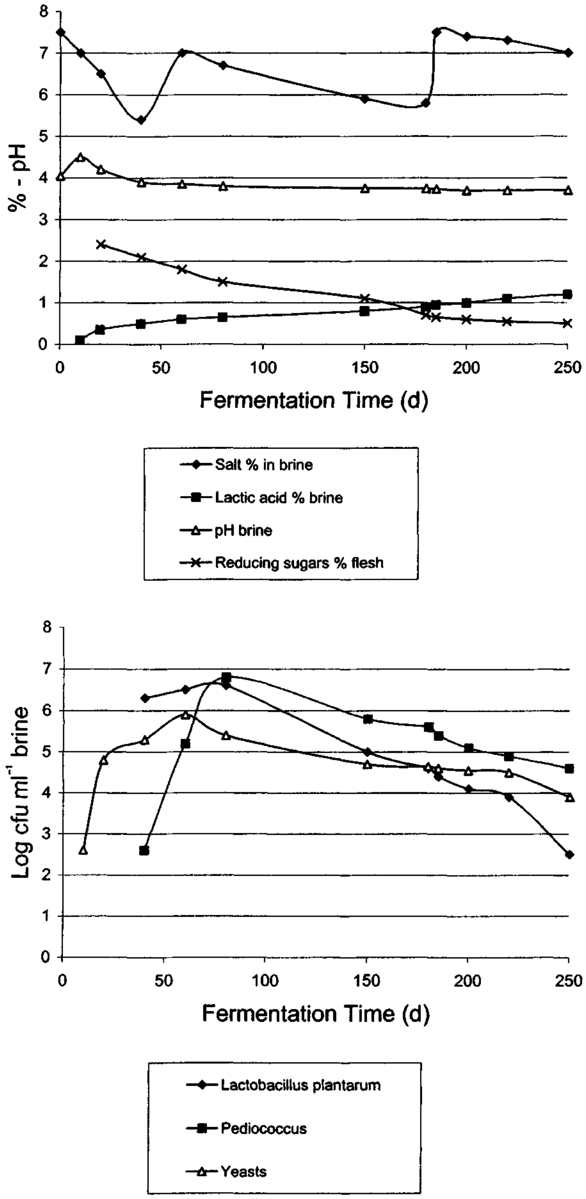

Figure 26-8 Chemical and Microbiological Changes during the Traditional Fermentation of "Treated Green Olives in Brine." *Source:* Data from P. Garcia Garcia et al., Lactic Fermentation during the Storage of "Alorena" Cultivar Untreated Green Table Olives, *Journal of Applied Bacteriology,* Vol. 73, pp. 324–330, © 1992, Blackwell Science, Ltd.

Prevention of Spoilage

In the fermentation of treated green olives in brine, initial proliferation of gas-forming Gram-negative rods may cause "aleunbrado," also called gassy spoilage or floaters. This type of spoilage is characterized by blisters, causing the skin to separate from the flesh of olives and also by the formation of gas pockets. The problem may be avoided by adjusting the initial pH to values around 6.0 or less by bubbling CO_2. Further pH reduction of brine pH to 4–4.5 is achieved usually by adding acetic, lactic, or hydrochloric acid.

In untreated natural black olives, gassy deterioration may be caused by yeasts, such as *Saccharomyces* and *Hansenula.* Also, *Bacillus polymyxa* and *B. macerans* may develop with Gram-negative bacteria early in fermentation and cause softening by their pectolytic enzymes. Certain pectolytic yeasts, such as *Saccharomyces kluyveri* and *S. oleaginosus,* may also cause severe softening in such directly brined olives.

In treated black olives in brine pasteurization, which is used occasionally prior to oxidative darkening, may prevent texture loss due to the pectolytic yeasts. This will also kill vegetative cells of *Bacillus* spp. It is not known whether remaining endospores of *Bacillus* spp. are able to germinate under the prevailing environmental conditions.

In all types of olives, malodorous types of spoilage may be caused by various anaerobic microorganisms. A putrid smell may be the result of growth of proteolytic *Clostridium* spp. Butyric acid spoilage may arise from development of butyric acid bacteria, such as *Clostridium butyricum.* Hydrogen sulfide spoilage results from *Desulfovibrio aestuarii.* Another off-odor called "zapatera" is characterized by the eventual development of a foul fecal-like stench, and is caused by *Clostridium sporogenes* and other clostridia in association with *Propionibacterium* spp. Contamination of brined olives with these anaerobic bacteria may come from water, dust, fermenters, or other equipment used in processing, or possibly from the surface of the olives. Spoilage usually starts at the bottom of fermenters where anaerobic conditions prevail. Malodorous fermentation can generally be prevented by working under good sanitary conditions and by controlling pH (≤ 4.6) and salt concentration ($\geq 5\%$).

Control of Safety

The most important safety issue in fermented olives appears to be the risk of *Clostridium botulinum* growth and toxin formation. Whereas anaerobic spoilage may occur during initial or later process stages, the occurrence of *C. botulinum* appears, however, to be rare.[76] A low pH (≤ 4.4), or relatively high salt concentration ($\geq 7\%$ w/v NaCl), or their combination is regarded as adequate protection against botulism.[92,95] Lactic acid bacteria will have produced lactic and acetic acid in addition to a reduced pH; this provides additional antimicrobial effects caused by the undissociated acids.[59,99] However, if such basic compositional requirements are not fulfilled, botulism cannot be ruled out completely. For instance, black olives were incriminated in a small outbreak of botulism of the B type[36]; the composition of the olives was insufficiently reported to evaluate their quality in relation with the above remarks.

A protective effect of lactic acid bacteria can be achieved by their production of bacteriocins, eg, plantaricin[136] and sakacin[143]; however, these were found to be ineffective against *C. botulinum.*[62,134]

Another aspect of food safety is the control of pathogens such as *Salmonella.* Investigations on the inhibitory effect of oleuropein showed that this glucoside does not inhibit *S. enteritidis,*[155] thus for safety one has to rely on other factors.

Spanish-style (green) olives, as they are produced commercially, eg, in glass jars or plastic pouches, are usually not pasteurized. Their pH is in the range of 3.5 to 4.0, with 0.5% to 0.75% w/v free acidity expressed as lactic acid and their salt concentration varies between 5% and 8% w/v. To spiced or stuffed olives, potassium sorbate may be added to a concentration of up to 0.05% w/v as sorbic acid. In pasteurized green olives the pH is 4 to 4.2 and the salt concentration about 5.5% w/v. Treated black olives in brine are sterilized as their pH varies in the range of 5 to 8 and their salt concentration from 2.5% to 5% w/v. Natural black olives cannot be sterilized for reasons of texture loss. For this reason, their pH in retail products is kept below 4.6 and their salt concentration at 7% to 8% w/v. In addition, potassium sorbate is allowed in this product to a final concentration of 0.05% w/v as sorbic acid.

Olives may carry mold propagules. *Aspergillus flavus* strains were isolated from natural black olives in brine, and their ability to produce aflatoxins was tested.[30] Under suitable conditions (aerobic incubation), mold growth was significant on fresh, damaged black olives and their paste, but was only weak on intact black olives. Only low levels of aflatoxins could be produced by strong aflatoxigenic strains. This implies that the use of intact olives for processing is preferable; furthermore, the olives must be protected from mold growth in hermetically sealed containers.

26.2.5 Acidified Products

Method of Production

Acidified products or vinegar-pickled vegetables are prepared (Figure 26-9) by pouring preboiled, hot vinegar onto the vegetables. These may be whole or cut cucumbers, gherkins, beets, olives, onions, peppers, or other mixed vegetables.[10,24] Salt, spices and herbs, herb extracts, sugar, and chemical preservatives are usually added. Prior to pasteurization, large pieces such as whole cucumbers, are blanched to exhaust air pockets. For unfermented pasteurized pickles, a liquor is used to fill jars and cans so that the final product contains 0.5% to 0.6% w/v acetic acid and up to 3% w/v salt, while the pH is about 3.7.[44] These products are shelf-stable for more than 1 year. Unpasteurized refrigerated pickles have a shelf life of not more than 3 months, during which time a slow lactic fermentation seems to occur. Their microbial safety status is rather unclear.

In Europe, unfermented sweet-sour pickles of gherkins and silverskin onions, for example, are quite popular. The liquor used to fill cans and jars may contain 2.5% to 4% w/v acetic acid, 5.5% to 8% w/v sucrose, and 2% to 2.5% w/v NaCl. With a liquor content of about 40% w/w, the concentrations in the final product would be 1% to 1.6% acetic acid, 2.2% to 3.2% sucrose, and 0.8% to 1.0% w/w NaCl, respectively. The products are pasteurized (30 minutes for 1 liter jars) at a waterbath temperature of 80° to 85°C. These products may be stored for more than 1 year at temperatures preferably not exceeding 15°C to prevent undesirable softening.

Microbiological and Chemical Changes during Production

In fresh pack pickles, survival of the pasteurization treatment by thermoresistant bacterial endospores may be expected; these would not be able to germinate in the acid product. In refrigerated pickles, some yeasts and lactobacilli might be present in the product.

Prevention of Spoilage

In fresh pack pickles, the preservation is achieved by a combination of low pH and pasteurization, and a relatively low concentration of acetic acid will suffice. For fresh pack cucumber pickles (Figure 26-9), the canning operation (glass jars or large 10 liter cans) is essentially the same as for fermented cucumbers, but the pasteurization is slightly more severe (15 minutes at an internal temperature of 78°C).

However, if nonpasteurized refrigerated pickles need to be preserved without preservative, the acetic acid concentration should be minimum 3.6% v/v[23] and the pH should be 3.5 or below. A preservative such as sodium benzoate (max. 0.1% w/w[149]) is usually added, and the product is stored at 1° to 5°C. Under marginal conditions, hardy species of yeasts (*Saccharomyces bailii* and *Pichia* spp.) and lactobacilli might grow and cause spoilage.[131,146]

It seems possible that acidified pasteurized vegetables may be prone to spoilage by *Alicyclobacillus acidoterrestris*, an acidophilic mesophile with a pH optimum between 3 and 4 and a minimum growth temperature of 26°C. This and more thermophilic species of *Alicyclobacillus* have been incriminated in spoilage of fruit juices, but so far occurrence in acidified pasteurized vegetables has not been recorded.[17,148,165]

Control of Safety

The safety of pasteurized acid foods depends on pasteurization and the fact that the pH (lower than 4.5) combined with the presence of organic acids, prevents the growth of pathogenic microorganisms. The safety of refrigerated pickles depends on the combination of refrigerated storage, a pH lower than 4.5, and the presence of organic acids, salt, and preservatives.

However, it is prudent to realize that these are not sterile products, and that surviving pathogenic microbes might proliferate when pickles are used at low concentrations as ingredients in neutral pH foods.

26.3 CEREALS, TUBERS, AND ROOTS (STARCHY PLANT FOODS)

26.3.1 General Aspects

Range of Plant Materials Used and Products Produced

The most important starchy plant foods used in food fermentations are cereals, starchy tubers, and root crops. Table 26-7 provides an overview of starchy food plants that are processed into fermented foods for human consumption.

Cereals are grown worldwide, although a distinction can be made between tropical cereals (maize, millets, sorghum, rice) and those grown in moderate climates (wheat, rye, barley, oats).

Root crops and tubers are important suppliers of dietary starch. In root crops, the entire swollen root is edible, whereas tubers are swollen parts of the root system, or the stem. In both cases, the crop grows underground. The most important root crop is cassava, whereas sweet potato and Irish potato are major tuberous crops. Cassava is an extremely important staple food in tropical climates.

Range of Types of Fermentation

Table 26-7 summarizes a variety of fermented foods made from starchy food plants, their geographical origin, the principle of their manufacturing procedure, a description of the properties and utilization of the ready food, the microorganisms that dominate the fermentation, and references to the literature. By way of examples, products made of cereals (kenkey and sourdough) and of roots (gari) will be outlined in some detail in the following sections.

In order to obtain an edible fermented product from these food plants, a fermentation as well as a cooking step should take place. But in which sequence? In practice, both options are used.

In many "household-scale" fermentations in tropical countries, uncooked cereals and root crops are fermented first, and then cooked prior to consumption. Such products are listed under the first heading in Table 26-7: "cereals fermented prior to cooking," and "roots." In uncooked cereals and roots, endogenous enzyme activity generates adequate fermentable carbohydrates for a lactic acid fermentation to take place. Also, some starch-degrading bacteria and molds may contribute to the generation of fermentable carbohydrates from starch. Generally, lactic acid bacteria are poor degraders of starch. Consequently, it is essential for strong acidification that this enzymic amylolysis takes place. In many "household-scale" fermentations inoculation is not used. The minority of lactic acid bacteria on plant raw materials can achieve dominance at the conclusion of a natural succession of microorganisms. The climax population is formed by the most acid-tolerant, ie, lactic acid bacteria. Some examples of highly acid-tolerant species are *Lactobacillus fermentum*, *Lactobacillus plantarum*, *Pediococcus acidilactici*, and *Enterococcus faecalis*. A microbial succession takes time, and does not always produce the same result. A simple but very effective way of inoculation is the addition of previously fermented product to a new batch. This "back-slopping" approach causes the enrichment of high numbers of acid-tolerant lactic acid bacteria in the inoculum. Using back-slopping, lactic fermentation of cereals may be completed twice as rapidly as a fermentation without added inoculum. Cooking *after* fermentation and immediately before consumption inactivates any pathogenic bacteria, viruses, and parasites and increases the safety of the products. In many small-scale processes, hygiene is inadequate and in many tropical countries the quality of the water supply is not reliable.

Fermentation after brewing and cooking is required for the preparation of alcoholic beverages. In acidic conditions, fungi can develop well if their other environmental requirements are fulfilled. For mold growth, aerobic conditions are required, which explains the reason why lactic-fermented doughs become moldy on the surface if not protected adequately. On the other hand, when fermentable sugars are present, yeasts can develop in coexistence with lactic acid bacteria. This is the basis for a variety of traditional African beers made from maize, sorghum, or millets such as "busaa" and "pito."

Instead of using germinated grain (malt) to generate fermentable carbohydrates for brewing, mold enzymes are used in the saccharification of cooked rice for the preparation of Japanese rice wine (saké). The fermentation of saké consists of a mold solid-state phase, followed by a liquid fermentation dominated by yeasts and lactic acid bacteria.

In addition to these mixed fermented African and Asian alcoholic beverages, several popular European beers (Gueuze, Berliner white beer) are the result of inoculation with a combination of yeasts (*Saccharomyces*, *Brettanomyces* spp.) and lactic acid and other bacteria (*Lactobacillus*, *Pediococcus* spp.). The fermentation of some whiskey mashes is also of a mixed microbial character.

Fermentation after cooking the cereals or roots is used for lactic acid fermentations, and also for fer-

Table 26-7 Fermented Foods Made from Starchy Food Plants

Raw Material	*Name and Origin of Fermented Product*	*Principle of Manufacturing Process*	*Characteristics and Use of Product*	*Predominant Microorganisms*	*References*
Cereals fermented prior to cooking:					
Maize (*Zea mays*)	Mawè (Bénin)	Grind whole maize to grits, make dough by adding water, allow natural fermentation by LAB[a] and yeasts.	Sourdough, from which stiff porridges or dilute beverages are made (staple food).	*Lactobacillus fermentans, L. cellobiosus, Candida krusei*	58
Maize (*Zea mays*)	Uji (Kenya)	Dough maize grits with water, and allow natural lactic fermentation. Dilute and cook dough in boiling water to beverage of about 5%–7% dry matter.	Sour refreshing beverage, for breakfast, lunch, and snack. Also used as weaning food.	*Lactobacillus plantarum, L. fermentum, L. cellobiosus, L. büchneri, Pediococcus acidilactici, P. pentosaceus*	82
Maize (*Zea mays*)	Ogi (Nigeria)	Soak whole maize kernels in water; wet grind and lactic fermentation submerged in water; recover sour maize sediment and boil to thin beverage like Uji.	Same as uji.	*L. plantarum, L. confusus, L. murinus, L. agilis, Leuconostoc mesenteroides*	63
Maize (*Zea mays*)	Kenkey (Ghana)	Soak whole maize kernels in water; wet coarse grind, make stiff dough followed by lactic fermentation; cook half of the dough to gelatinized mass and mix with uncooked half; shape into balls, wrap in leaves, and cook submerged in water.	Massive, sour, bread-like maize product. In some areas, eaten 3 times daily (staple food).	Obligate heterofermentative lactobacilli, *Candida krusei, Saccharomyces cerevisiae*	50, 61
Sorghum (*Sorghum bicolor*)	Kisra (Ethiopia)	Sorghum flour mixed with water, inoculated with starter dough (previous batch), fermented, and baked.	Flat bread, used as starchy staple food.	*L. fermentum, L. reuteri, L. amylovorus, Candida krusei*	51
Wheat (*Triticum vulgare*) Rye (*Secale cereale*)	Sourdough (Europe, US)	Whole wheat/rye flour mixed with water, inoculated with previous batch of sourdough, fermented by mixed lactic acid bacteria and yeast populations.	Sour, stiff dough, used as leavening agent in the preparation of dough for sourdough bread preparation.	*L. plantarum, L. casei, L. büchneri, L. acidophilus, L. alimentarius, L. farciminis, L. delbrückii, L. fermentum, L. brevis, L. sanfrancisco*	137

Raw Material	*Name and Origin of Fermented Product*	*Principle of Manufacturing Process*	*Characteristics and Use of Product*	*Predominant Microorganisms*	*References*
Wheat (*Triticum vulgare*)	Tarhana (Turkey) Trahana (Greece)	Make dough with wheat flour, yogurt, bakers' yeast, tomato paste, onion, salt, peppers; ferment, dehydrate, grind, sieve.	Shelf-stable nutritious soup base.	*Saccharomyces cerevisiae, Streptococcus thermophilus, L. bulgaricus, L. lactis ssp. lactis, L. casei, L. lactis ssp. diacetylactis, Leuconostic cremoris*	60
Rice (*Oryza sativa*)	Idli (India)	Grind rice with bengal gram, add water, allow natural fermentation, prepare steamed cakes.	Steamed cake (staple food).	*Leuconostoc mesenteroides, Enterococcus faecalis,* yeasts	65, 66, 159
Rice (*Oryza sativa*)	Men (Vietnam) Ragi (Indonesia)	Make dough of uncooked rice flour, water, garlic, spices, and add previous batch; shape to small balls or tablets and allow to ferment and sun dry.	Used as fermentation starter for tapé, saké, and similar fermented rice products.	*Amylomyces rouxii, Endomycopsis fibuliger, Hyphopichia burtonii, Pediococcus* spp., *Lactobacillus* spp.	70, 96
Cereals fermented after brewing and cooking:					
Sorghum (*Sorghum bicolor*) Finger millet (*Eleusine coracana*)	Pombe (E. Africa) Busaa (Kenya)	Make dough with maize grits, allow natural fermentation by LAB and yeasts; fry soured dough on hotplate, mix gelatinized crumbs with ground germinated millet and water; brewing and fermentation by yeasts and LAB occur simultaneously.	Turbid, sour beer with considerable nutritional value.	*L. plantarum, Saccharomyces cerevisiae*	93
Maize (*Zea mays*) Sorghum (*S. bicolor*)	Pito (Ghana)	Wort is made from malted sorghum and water, a yeast-LAB starter (enrichment) is added, followed by alcoholic fermentation.	Turbid, sour beer.	Lactic acid bacteria, *Saccharomyces, Candida* spp.	25, 144
Rice (*Oryza sativa*)	Saké (Japan)	Steam-cook rice, inoculate with starter (ragi, men, or similar), ferment until fully liquefied, filter.	Rice wine.	*Aspergillus oryzae, Leuconostoc mesenteroides* var. *sake, L. sake, Saccharomyces cerevisiae*	168

Cereals fermented after cooking:					
Maize (*Zea mays)*	Maheu (S. Africa)	Cook maize grits in water, cool, inoculate with wheat bran and LAB (*L. delbrückii*), ferment at about 50°C	Refreshing sour beverage.	*L. delbrückii, L. bulgaricus*	57
Maize (*Zea mays)*	Togwa (Tanzania)	Suspend maize grits in water and cook to porridge; add milled germinated sorghum (malt) and some of previous batch of togwa; allow to ferment.	Refreshing sour beverage.	*L. lactis, Lactobacillus* spp., *Candida krusei*	68
Maize (*Zea mays*)	Pozol (Mexico)	Boil whole maize in lime water, dehull, grind to dough, shape into balls, wrap in leaves, allow lactic-fungal fermentation. Make pozol by suspending fermented ball in water.	Beverage.	*Leuconostoc, Lactobacillus, Candida* spp., *Trichosporon cutaneum, Geotrichum candidum*	106, 161
Glutinous rice (*Oryza sativa* var. *glutinosa*)	Tapé ketan (Indonesia)	Prepare steamed glutinous rice, sprinkle crumbled starter (see ragi) on it, cover, ferment.	Sweet, sour, and alcoholic rice snack.	*Amylomyces rouxii, Hyphopichia burtonii, Pediococcus* spp.	74
Rice (*Oryza sativa*)	Risogurt (Korea)	Extrude rice flour, add soyabean protein isolate, ferment with LAB to yogurt-like product.	Refreshing and nutritious sour beverage.	*Streptococcus thermophilus, Lactobacillus bulgaricus*	160
Roots:					
Cassava (*Manihot utilissima*)	Gari (Nigeria)	Wash, peel, grate cassava to pulp; press pulp in woven bag, allow to drain juice and ferment; roast fermented crumbs to dry, gelatinize starch, and remove HCN.	Instant starch food, eg, for breakfast; shelf-stable staple food.	*Leuconostoc, Enterococcus, Lactobacillus, Geotrichum candidum*	116, 164
Cassava (*M. utilissima*)	Kokonte (Ghana)	Wash, peel, cut cassava, cover, allow solid-substrate fermentation; pound and cook.	Stiff cooked dough; staple food.	Lactic acid bacteria, molds (*Rhizopus, Neurospora* spp.)	78
Cassava (*M. utilissima*)	Attiéké (Ivory Coast)	As gari, but steam cooked after fermentation.	Ready-to-consume cooked crumbs; staple food; not shelf stable.	See gari	39
Cassava (*M. utilissima*)	Farinha de Manioca (Brazil)	Wash, peel, sour fermented starch, sun dried.	Flour used to cook stiff pasty dishes.	See gari	27

mentations with mixed fungal starters (eg, tapé ketan and tapé ketella). Important consequences of cooking first are: (1) the gelatinization of the starch causes a considerable increase of viscosity, which makes the product more difficult to handle, (2) the endogenous enzymes are inactivated and thus, no auto-amylolysis will occur, and (3) the epiphytic microorganisms are killed. Consequently, if a fermentation must follow, a source of fermentable carbohydrates and the right type of functional microflora must be provided. In Togwa, for example, this is achieved by adding germinated sorghum (malt) to the cooked maize. The enzyme activity of the malt will generate maltose from the maize starch; moreover, sorghum malt contains high levels of bacteria and yeasts, and thus it provides a mixed inoculum. However, the quality of this inoculum leaves much to be desired from the points of view of safety and product quality. In Maheu, a more controlled process is achieved. Addition of wheat bran (containing cereal enzymes) ensures generation of fermentable carbohydrates, whereas the fermentation takes place with a selected thermophilic lactic acid bacterium at about 50°C. In practice, this temperature is selective for *Lactobacillus delbrückii* and is too high for enteropathogenic bacteria to survive. A similarly controlled process is that of risogurt, in which rice is cooked to gelatinize, partly degraded using amylolytic enzymes, sterilized by autoclaving, and fermented with a defined, mixed culture.

Status

Fermented cereal and root products are known and consumed worldwide. They are often used as staple foods in tropical countries. Production may be on a household scale and sales may serve as a source of (additional) income to the family. Alternatively, some products (such as uji, sourdough, pombe, saké, maheu, and gari) are also processed on an industrial scale facilitating some control of microbiological and chemical changes, and of the microbiological safety of the products.

Composition of Starting Material

Ranges of chemical components of starchy foods are listed in Table 26-8. Cereals contain 25% to 30% moisture at harvest, and drying to 10% to 14% moisture content makes them rather stable for storage. Cereals are seeds and consist of an embryo, an endosperm, and multiple protective layers referred to as "bran." Whereas the embryo has a relatively high lipid and protein content, the endosperm contains the reserve nutrients mainly in polymeric, water-insoluble form (starch, protein, lipids). The bran has a rather high cellulose and hemicellulose content, and significant levels of silicate and minerals (ash). Other important compounds in cereal endosperm and bran are phytic acid (inositol hexa phosphate) and tannins (condensed polyphenols). Both substances can form chemical complexes with minerals, starch, and proteins; as a result, they have a negative effect on a number of important processes. First, they reduce the bioavailability of minerals in the digestive tract; as such they are regarded as "antinutritional factors (ANFs)." Moreover, the tendency of phytic acid and tannins to bind with proteins also causes inhibition of enzymes and metabolic activities of microorganisms. During the germination of seeds, a variety of saccharolytic, proteolytic, and other enzymes are activated and/or produced mainly from within the aleurone layer of the bran. The result is that the endosperm material is "modified," ie, polymeric material is degraded to oligomers and further to maltose, small peptides, and free amino acids, for example. During germination, ANFs such as phytic acid are degraded. This enzymatic degradation also takes place in grains that have been ground to a meal that is mixed with water. Obviously, this type of bioconversion can only take place in cereals that have not previously been heated.

Roots and tubers have a much higher moisture content and contain considerably less protein than cereals. Unlike cereals, they are highly susceptible to spoilage. Bitter varieties of cassava contain toxic glycosides. Particularly in Africa, these bitter varieties are widely preferred by farmers as they are much less affected by wild animals (monkey, bush pig) and theft. The toxic glycosides (linamarin, lotaustralin) can be degraded to glucose, acetone, and the highly toxic HCN if they are brought into contact with the enzyme linamarinase. In the intact root, the cell membrane–bound enzyme is physically separated from linamarin. However, accidental or deliberate damage to the root tissue starts the enzymatic process. This is important during food processes aimed at detoxifying bitter cassava.

Cereals, roots, and tubers carry a mixed soilborne and airborne microflora, characterized by the presence of bacteria (eg, *Enterobacter aerogenes*, *Erwinia* spp., *Bacillus mesentericus*, and *Flavobacterium* spp.), yeasts (eg, *Cryptococcus albidus*), and molds (*Fusarium*, *Aspergillus*, *Penicillium*, *Rhizopus*, and *Neurospora* spp.). Lactic acid bacteria are present but in very low numbers. Much of this original flora is removed during preparatory processing, for example, by peeling, dehulling, and washing.

26.3.2 Fermentation of Maize To Produce Kenkey

Kenkey is the major staple food of Ghana. It is eaten as a kind of maize bread at almost all mealtimes. Kenkey is produced at household level in small batches (5 to 10 kg), but usually in larger quantities (batches of 100 to 2,000 kg) by cottage enterprises and women's cooperatives.

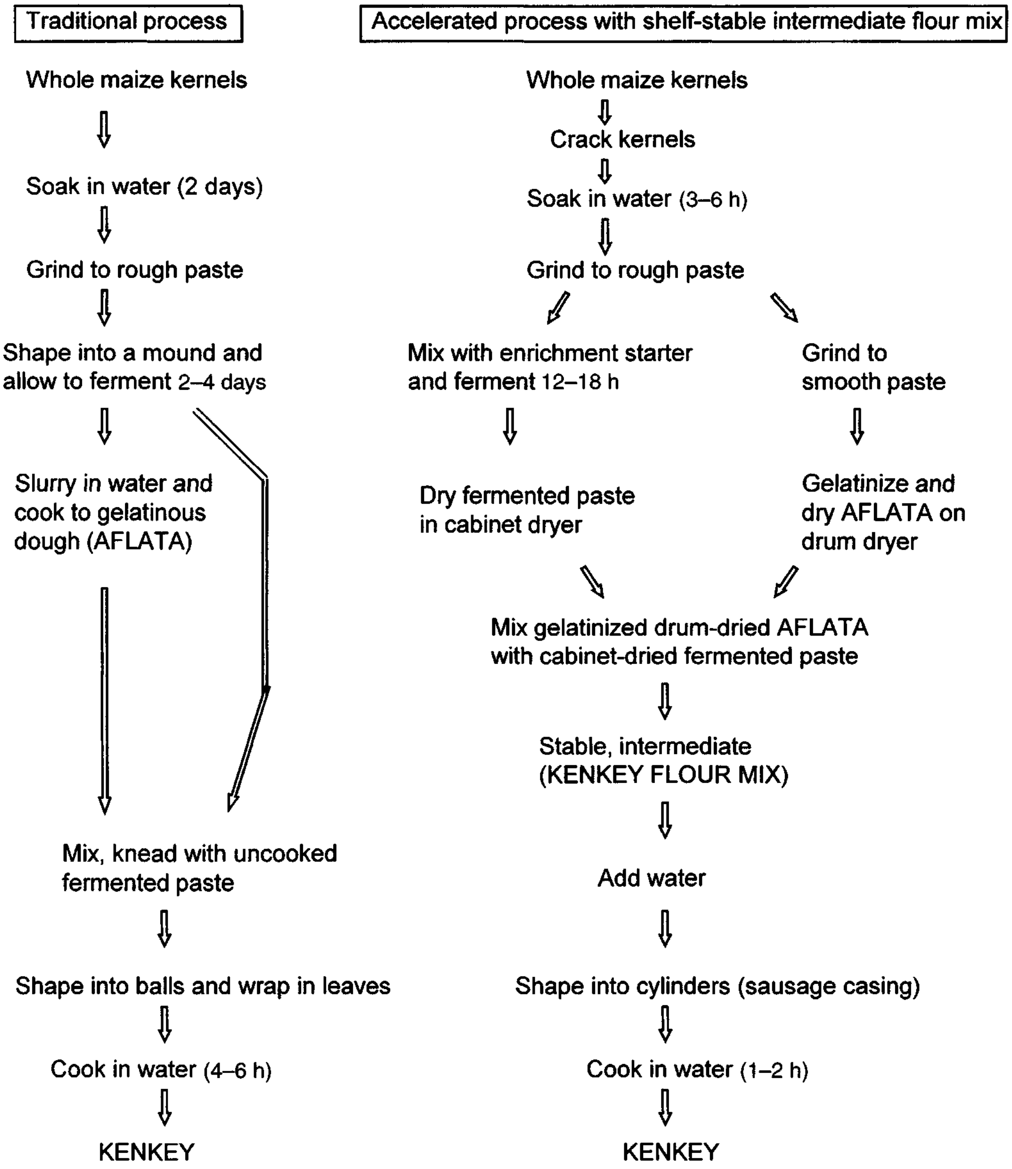
Method of Production

Figure 26-10 shows the sequence of operations of the traditional process. Whole maize is cleaned, soaked, ground roughly, and made into a dough that is fermented at ambient temperatures (25° to 30°C). No starter is used for this fermentation, but it may be presumed that the use of the same equipment and containers may result in the development of a "house flora" that facilitates the onset of the fermentation. The fermented dough is divided into two equal parts, one of which is mixed with water and cooked to gelatinization. This sticky gel (aflata) is mixed and kneaded with the remaining half; aflata serves as cement and moisturizer in the resulting dumpling. This is shaped, wrapped, and cooked immersed in water. Traditional processes demand much time, physical labor, and fuel energy. Technological interventions, as shown in Figure 26-10, can help to accelerate the process and to achieve a shelf-stable intermediate flour mix, which can be turned into fresh kenkey rather quickly. In this case, the water uptake period is shortened by precracking the kernels, and a starter of lactic acid bacteria is used to speed up the fermentation. As there is much interest in time-reducing and shelf-stable consumer products, a dehydrated mix of fermented dough and pre-cooked and drum-dried aflata has been developed, which can be made into kenkey in relatively short time.

Microbiological and Chemical Changes during Fermentation

Figure 26-11 shows the development of lactic acid bacteria and yeasts in the fermenting dough. Molds and catalase-positive bacteria are present in maize, but disappear during the fermentation. Dominating lactic acid bacteria include *Pediococcus cerevisiae*, *Leuconostoc mesenteroides*, and *Lactobacillus fermentum*. Dominating yeasts are *Candida krusei*, and *Saccharomyces cerevisiae*. Dominating molds (during the initial stages and not regarded as functional flora) are: *Penicillium citrinum*, *Aspergillus flavus*, *A. parasiticus*, *A. wentii*, and *Fusarium subglutinans*.

During the fermentation, several chemical changes take place that are catalyzed either by the microorganisms, or by the endogenous enzymes of maize. In Table 26-9, approximate analysis at key processing stages is presented. During the process, the moisture content increases due to the soaking and cooking. While no significant changes occur in crude protein, ash, fiber, and carbohydrates, there is a marked increase of available lysine. As this essential amino acid is limiting in maize, an increase improves the nutritional value of the product. The bioavailability of nutrients is limited by the antinutritional factors phytate, polyphenols, and lectins, which can form chemical complexes with minerals, proteins (including enzymes of the digestive tract), and sometimes with starch. The reduction of the phytate content (Table 26-9) increases the bioavailability of minerals and proteins. The required phosphatase activities have been demonstrated in lactic acid bacteria and are present also as endogenous activity in several plant tissues. Consequently, phytate degradation is not al-



Traditional process
Whole maize kernels
Soak in water (2 days)
Grind to rough paste
Shape into a mound and allow to ferment 2–4 days
Slurry in water and cook to gelatinous dough (AFLATA)
Mix, knead with uncooked fermented paste
Shape into balls and wrap in leaves
Cook in water (4–6 h)
KENKEY
Accelerated process with shelf-stable intermediate flour mix
Whole maize kernels
Crack kernels
Soak in water (3–6 h)
Grind to rough paste
Mix with enrichment starter and ferment 12–18 h
Grind to smooth paste
Dry fermented paste in cabinet dryer
Gelatinize and dry AFLATA on drum dryer
Mix gelatinized drum-dried AFLATA with cabinet-dried fermented paste
Stable, intermediate (KENKEY FLOUR MIX)
Add water
Shape into cylinders (sausage casing)
Cook in water (1–2 h)
KENKEY

Rombouts, Dry Milling and Accelerated Fermentation of Maize for Industrial Production of Kenkey, a Ghanaian Cereal Food, *Journal of Cereal Science,* Vol. 20, pp. 291–298, © 1994, Academic Press Ltd.

ways purely the result of microbial activity. The effect of fermentation on the pasting behavior is also of interest: the texture and cohesion of the cooked product is favored by high peak and set-back viscosities. Important volatile flavor compounds in maize dough fermented with lactobacilli include acetic acid, acetoin, 2,3-butanediol, butanoic acid, lactic acid, 3-methylbutanoic acid, octanoic acid, 2-phenylethanol, and propanoic acid.[50]

Prevention of Spoilage

Traditional kenkey is at risk of mold spoilage during the fermentation of the dough. Superficial mold growth occurs on the dough; this may lead to off-colors, off-taste, and possibly mycotoxin formation. It is important therefore to achieve the lactic acid fermentation as quickly as possible, thereby reducing the available time for the onset of mold growth.

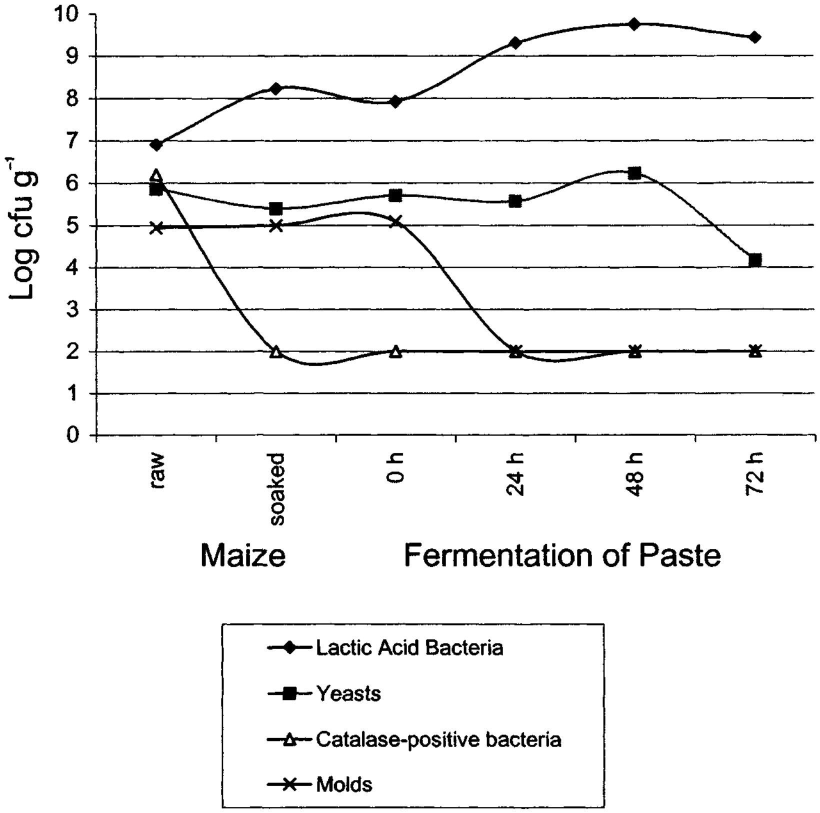


Figure 26-11 Microbiological Changes during the Traditional Kenkey Fermentation Process. *Source:* Data from references 18, 50, 61.

Once wrapped and cooked, kenkey is reasonably well protected against post-processing contamination, and has a shelf life of several days at ambient temperatures, provided the wrapping has not been opened. However, the average consumer will not store kenkey for longer than a day, as staling of the cooked maize gel renders it less palatable.

A long shelf life may be expected from a fermented and dehydrated product (Kenkey-Flour-Mix, Figure 26-10). As a result of dehydration, some losses of volatile organic acid (acetic acid) and esters occur, which might affect the flavor. Drum drying of aflata at 140°C for 0.5 minute reduced the available lysine from 2.36 to 1.59 g 16 g N^{-1}, whereas cabinet drying at 60°C for 3 hours caused no reduction.[88,89] The conclusion is that shelf-stable products can be made, but at the expense of thermal energy, nutritional value, and possibly flavor.

Control of Safety

In general, fermentation improves nutritional properties, makes foods attractive, safeguards food against pathogens, and preserves food. The formation of organic acids and other antimicrobial metabolites, and the competitiveness of actively growing fermentation starters contribute to the destruction or inhibition of bacterial pathogens. Moreover, fermentation usually takes place in the presence of antimicrobial ingredients (spices, salt), or in the context of a sequence of treatments (washing, grinding, cooking, drying). The combined effect of these treatments with fermentation can further increase the safety of food.

In the production of kenkey, the use of maize as raw material always carries the risk of being contaminated with aflatoxins, as well as other mycotoxins, eg, fumonisins. Although some reduction of the mycotoxin levels may be expected from treatments such as soaking and cleaning, lactic acid bacteria have very little impact on the chemically stable molecules of aflatoxins and fumonisins. It is thus essential that the raw material be free of mold growth.

The antimicrobial activity caused by the combined effects of acids, compounds sensitive to pro-

teolytic enzymes, and other compounds with antimicrobial activity was stronger in mixed culture naturally fermented than in single pure culture fermented kenkey. This means that introduction of pure cultures as starters may impose a risk to the microbiological safety of the product.[113]

As maize contains approximately 10% protein, this could serve as a precursor for the formation of toxic biogenic amines such as histamine. However, there is evidence that levels of biogenic amines in kenkey are well below tolerable levels (about 200 mg kg^{-1} for histamine).[95,105]

In conclusion, kenkey may be regarded as a relatively safe product, providing the raw material was of good quality and the lactic acid fermentation has been rapid. A main reason for the safety of this product is that it is cooked in its packaging material before consumption.

26.3.3 Fermentation of Cereal Flours To Produce Sourdough

Method of Production

Wheat doughs obtain their characteristic elastic and extensible properties from the wheat gluten proteins. The fermentation of wheat dough with added bakers' yeast, *Saccharomyces cerevisiae*, and its subsequent transformation into bread, is discussed in Chapter 28. Despite their lack of elastic gluten, other cereals can also be made into doughs. Rye, for instance, is used as a bread cereal despite its gluten deficiency. As rye doughs tend to form firm gels at reduced pH, the dough and baking properties of rye are enhanced by acid conditions such as prevail in sourdough bread.

Figure 26-12 shows the principle of the manufacture, maintenance, and utilization of sourdough in bread making. Many regional variations occur, but all within the general principles. Sourdough starter cultures are added as pure cultures or spontaneously fermented dough to a fresh flour-water mixture. Depending on temperature, dough yield (water content), presence of salt, and level of inoculation, the fermentation will proceed for 2 to 12 hours at temperatures ranging from 18° to 30°C. Inoculation is often performed with 5% to 10% w/w of previously fermented dough. This practice is referred to as "back-slopping." As a leavening agent in bread making, 10% to 20% w/w of mature (fermented) sourdough is added as dough ingredient. The addition of salt to the bread dough will reduce the speed of fermentation, so usually dough fermentations (carried out in subsequent stages at different temperatures) take a total of 3 to 10 hours. As a result of the activities of lactic acid bacteria and yeasts, gas will be produced as well as organic acids and volatile flavor components. The ratio of lactic:acetic acid is referred to as fermentation quotient (FQ). Higher concentrations of acetic acid result in a sharper sour taste and longer shelf life.

Microbiological and Chemical Changes during Fermentation

Cereal sourdoughs are enrichment cultures of relatively stable combinations of yeasts and (mainly) heterofermentative lactic acid bacteria. Depending on the type and composition of the flour, dough-making conditions, and incubation environment, rather characteristic mutualistic combinations develop during the long periods (months or years) that sourdoughs are maintained. Typical lactic acid bacteria and yeasts encountered are listed in Exhibit 26-1.

Wild strains of sourdough lactobacilli are specialized toward assimilation of maltose, the major assimilable carbon source in cereal dough.[167] A regular supply of maltose is generated by the endogenous cereal amylases. In principle, sugar transport in lactic acid bacteria can occur via (1) high affinity primary transport or phosphoenolpyruvate:sugar phosphotransferase systems both at the expense of ATP and inhibited at pH <6; or (2) low affinity secondary transport systems driven by (electro)-chemical gradients, which are effective at relatively high sugar concentrations. In maltose-grown *L. sanfrancisco* maltose uptake is via maltose-H^+ symport, thus at lower pH the proton-motive force will be increased and so will be the maltose uptake. Within the cell, maltose is phosphorylated and split into glucose-1P and free glucose. About 50% of the latter leaves the cell through a glucose uniport.[87] When all maltose has been taken up, the exported glucose will be assimilated in pure cultures. However, in sourdough the released glucose will be assimilated by yeasts. In sourdough, glucose is exported at the same rate as maltose is imported, reaching glucose levels up to 13 mM.[153]

In the presence of sufficient maltose, maltosephosphorylase, produced by lactobacilli, is not glucose-repressed. This factor is considered essential for the domination of the lactobacilli over microorganisms competing for the same carbon source (ie, maltose). As most other maltose-assimilating organisms are glucose-repressed, the export of glucose would thus serve as an indirect and temporary inhibitor. Nevertheless, maltose-assimilating *S. cerevisiae* competes with *L. brevis* ssp. *lindneri* resulting in re-

duced bacterial growth and organic acid production.[49] It was also suggested that lactic acid bacteria may produce antibiotics and thus support the stability of the sourdough population, but no direct evidence has been presented to confirm or contradict this hypothesis. Most yeasts present in sourdough are quite robust. They tolerate the concentration of acids present, but they do not appear to compete with the lactic acid bacteria because most of the prevailing species cannot assimilate maltose.

Yeasts may have a role as suppliers of growth factors; *S. cerevisiae* and *S. exiguus* excrete alanine, glutamic acid, leucine, and valine during the stationary phase of growth, and these amino acids stimulated growth of *L. brevis* ssp. *lindneri.* Lactic acid bacteria from sourdoughs require vitamins and varying numbers of amino acids, which could be supplied either by soluble matter from fresh yeast, a peptide, or live yeast cells.[94] It was also observed that in wheat doughs, proline and arginine are assimilated faster by mixed yeast–lactic acid bacteria cultures than by the individual microbial components. However, considerable levels of free amino acids are generated in dough by proteolytic enzymes of the cereal grain, and yeasts (*S. cerevisiae*) consume, rather than release, amino acids.[19] It appears that the extent of acidification of lactic fermentations of cereal doughs will, *inter alia,* depend on the availability of micronutrients for lactic acid bacteria. If the latter are deficient in the raw material to be fermented, they will have to be supplied by yeast cells. Consequently, an equilibrium situation will be established with final pH values and acetic acid concentrations enabling adequate yeast growth. It remains still to be clarified to what extent yeasts play a role as growth stimulators for sourdough lactic acid bacteria.[97]

Table 26-10 shows data illustrating the kinetics of acidification. At higher fermentation temperatures, the fermentation quotient (FQ) is usually higher (up to 5–7).

Prevention of Spoilage

The shelf life of bread is affected mainly by two microbiological aspects, namely mold growth and ropiness. Mold growth by *Rhizopus nigricans, Neurospora sitophila, Aspergillus,* and *Penicillium* spp. is most common on bread. The presence of organic acids, mainly acetic acid, that are undissociated at the prevailing pH (3.5–4.5), will delay the onset of mold spoilage in sourdough bread. Also, wrapping

bread in water vapor–permeable kraft paper, rather than in plastic bags, delays mold growth.

Ropiness in regular yeast-leavened bread is a type of spoilage that is caused by survival and growth of *Bacillus subtilis* and *B. mesentericus*, which produce capsular materials and degrade bread protein and starch, resulting in a sticky, threadpulling crumb with a typical pineapple smell. In sourdough bread, this type of spoilage occurs only very seldom because the sensitivity to heat of *Bacillus* spores is significantly increased at the pH prevailing in sourdough, compared with that in pH-neutral doughs. The maximum crumb temperature (usually occurring during 15 to 30 minutes) during baking is approximately 97°C, and decimal reduction times of *B. subtilis* spores at 97°C were determined in sourdough (Table 26-11). Sourdough was made with a representative inoculation level of 10% mature sourdough as a starter. After fermentation and baking, the resulting bread was incubated for 1 week at 37°C.

The data show that regular sourdough bread has an adequate antimicrobial effect to prevent ropiness. At the low level of contamination, the ratio lactic:acetic acid was not critical; at the higher level of *B. subtilis* only the lower FQ (signifying more acetic acid) was effective.

26.3.4 Fermentation of Cassava To Produce Gari and Similar Products

Method of Production

Cassava is highly perishable. In addition, bitter cassava varieties contain potentially toxic substances. Processing of cassava therefore has two major objectives: prolongation of shelf life by dehydration, and detoxification by degradation of the toxic principles prior to dehydration. Additional objectives include the formation of desirable smell and taste. Figure 26-13 illustrates the major steps involved in the production of gari, lafun, and mold-fermented cassava flour.

Cassava processing for detoxification involves some degree of size reduction combined with submerged fermentation. After peeling, the roots are cut into pieces and stored under water for several days, during which a retting process takes place. The softened cassava pieces are taken out of the water, sun dried, and subsequently milled to flour (eg, Nigerian "lafun"), or used to prepare creamy moist pastes such as "fu-fu."

Alternatively, for gari production, washed and peeled cassava can be grated to pulp and left to ferment in jute bags under pressure to exclude air. All fermentations take place at ambient temperatures (25°–35°C), and are carried out on a household or cottage scale in batches of several hundreds of kilos. Gari is also made on a semi-industrial scale producing several tons daily. On all scales of processing starters are used. These usually consist of fermented material of a previous batch. After fermentation of the pulp, it can be steamed for direct consumption (Ivorian "attiéké") or dry roasted to yield a dry pregelatinized instant breakfast meal (Nigerian "gari").

In several African countries, a solid-substrate fermentation process is carried out at the farm level. Cassava roots are washed, peeled, and cut into large pieces. These are made into a big heap, which is kept covered for a few days with a plastic sheet or suitable leaf material. When sufficient mold growth has occurred (criteria used are color, caused by mold sporulation, and odor) the cover is removed, the pieces are

scraped to remove excessive mold, and spread out in the open to dry. Finally, the pieces are ground to a flour, which is used to prepare cooked porridges.

Microbiological and Chemical Changes during Fermentation

The submerged fermentation of cassava pieces in water during the preparation of lafun is dominated first by homofermentative lactic acid bacteria (eg, *Lactobacillus plantarum*) followed by heterofermenters (*L. brevis*). *Clostridium* spp. usually occur in retted cassava; they are responsible for the typical butyric acid flavor,[12] and possibly also for the softening of the cassava tissue.

During fermentation of cassava pulp for gari production lactic acid bacteria (including *L. plantarum* and *L. brevis*) dominate during the fermentation, but other bacteria (*Bacillus*, *Staphylococcus* spp.) and yeasts have been found also in fermented pulp (Table 26-12).

As a result of lactic acid fermentation, the pH decreases and acid is formed at the expense of reducing sugars (Table 26-13). The flavor added by the fermentation adds to the popular taste of the product. Gari consists mainly of carbohydrates (starch) (Table 26-13). Swelling capacity is an important quality characteristic of gari. Having been roasted, its starch component has gelatinized and the product will absorb water readily, like an instant breakfast cereal. The higher the swelling capacity, the better the palatability of prepared gari.

During the sweating period in the production of mold-fermented cassava flour, moisture migrates from the center of the cassava pieces to the surface, but the cassava will retain sufficient water to enable a profuse microbial growth, consisting of rapid-growing molds (*Rhizopus*, *Neurospora* spp.) and bacteria (eg, *Bacillus* spp.). Cell wall degradation occurs as a result of fungal and bacterial enzyme activity, resulting in considerable softening.

Prevention of Spoilage

The shelf life of gari depends mainly on its water activity. Good quality gari has a water activity of 0.5–0.7 and a shelf life of 3 to 6 months. Table 26-14 lists a number of molds frequently encountered in gari. When added as a pure culture to gari that had been previously moistened, the fast-growing *Rhizopus* caused deterioration in 2 days; other slower-growing molds (*A. niger*, *A. candidus*, *A. tamarii*, *A. versicolor*, *A. flavus*, and *Cladosporium* spp.) needed 3 days. Adequate packaging is also essential to keep the water activity of the dry product low. In practice, industrially produced gari is bagged in woven polypropylene bags for distribution, and in polythene bags for retail purposes. Preferred traditional storage in the household is in recycled hermetically sealed tins.

Control of Safety

Consumption of raw, or inadequately processed, bitter cassava varieties may lead to ingestion of prussic acid (HCN). Mastication of raw cassava tissue containing linamarin and/or lotaustralin initiates the endogenous enzymic degradation of the glycoside, releasing unstable cyanohydrin that splits into acetone and HCN. Incorrectly processed cassava may contain residual levels of HCN. The toxic effects of HCN can be chronic at low doses, leading to paralysis and iodine deficiencies with concomitant symptoms of cretinism and mental retardation. Acute HCN intoxication may lead to respiratory failure and death. Thus, the main safety issue with

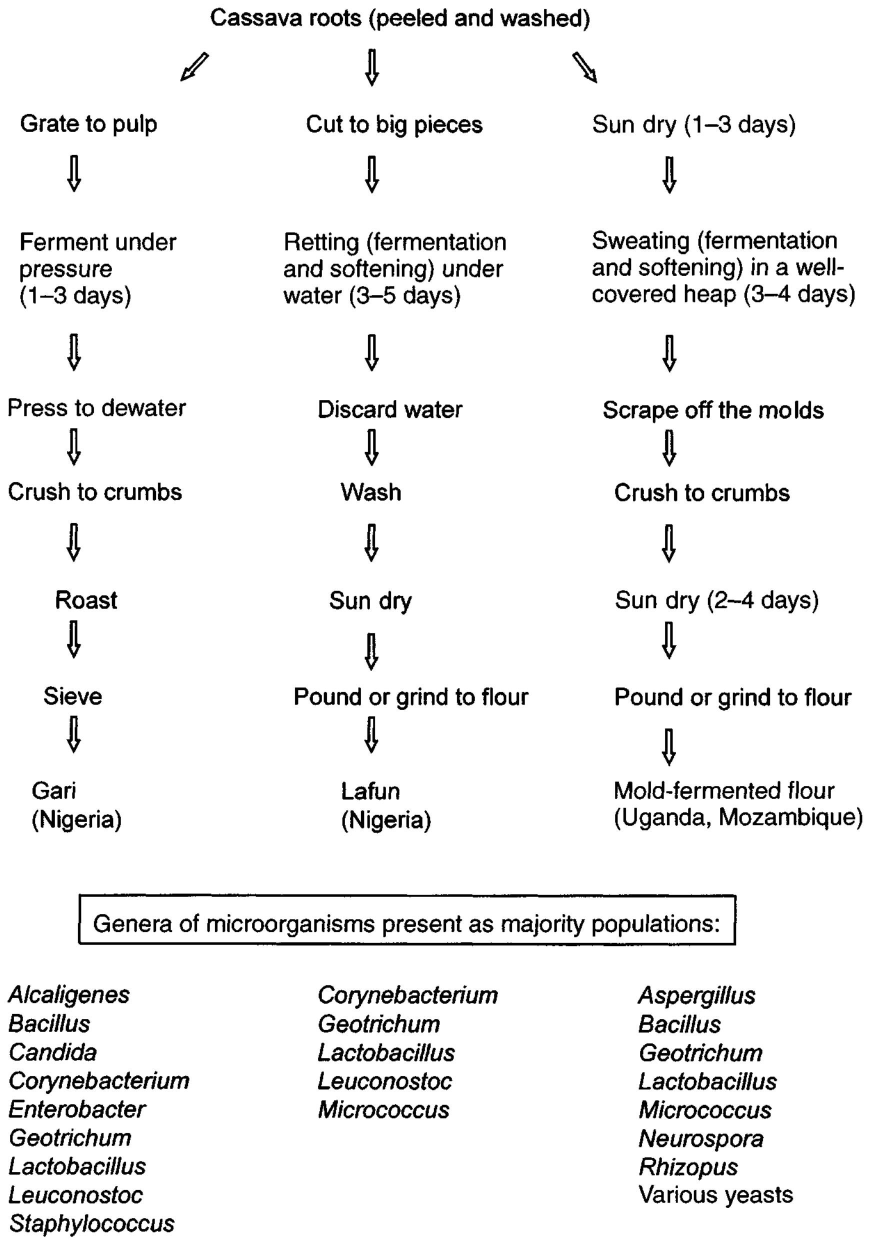

Figure 26-13 Prodution of Fermented Cassava Products and Major Microorganisms Involved. *Source:* Data from references 3,11,32–34,115,164.

cassava products is whether adequate detoxification of the cyanogenic glycosides has been achieved.

Within the cassava root, the cyanogenic glycosides are distributed unevenly, but they are present in all parts of the root, and are located in the cytoplasm. The endogenous enzymes able to degrade them (glycosidases, linamarinases) are cell-membrane bound, but come into contact with the glycosides upon loss of integrity of the cell due to mechanical damage (cutting, grinding) or enzymic degradation (physiological reactions leading to wilting, or microbial retting).

Although cassava can be fermented in different ways, experimental evidence shows that in gari, cyanide removal is a consequence of the activity of naturally occurring plant enzymes and process operations rather than microbial activity. Although about 50% of the lactic acid bacteria in fermenting cassava pulp are able to degrade linamarin, the microbial effects on linamarin are negligible during

Table 26-12 Microbiological Changes during the Manufacturing Stages of Gari from Cassava

this type of fermentation, and acidification is inhibitory to the degradation of linamarin by endogenous plant enzymes. In other cassava products, such as lafun and fungal fermented flour, molds soften the plant tissues, thus facilitating the reduction in cyanogen content.

Table 26-15 summarizes data on levels, toxicity, and Codex Alimentarius recommended standards for cyanide in gari, and the effect of gari processing on cyanogenic substances in sweet and bitter varieties. In both types of cassava, detoxification is achieved after grating. Industrial-scale processing with finer grating and better squeezing of the plant juice (by screw press) results in lower residual cyanide levels than traditional production. In both cases, bound cyanide has been more or less detoxified; residues consist of free HCN and are in line with the recommendation.

26.4 LEGUMES, OILSEEDS, AND TREEBORNE SEEDS (PROTEINACEOUS PLANT FOODS)

26.4.1 General Aspects

Range of Plant Materials Used and Products Produced

Leguminous seeds, oilseeds, and, to some extent, treeborne seeds are used as a source of dietary protein.

Especially when animal proteins are less available or too expensive, plant proteins may serve as meat substitutes. Table 26-16 provides an overview of proteinaceous plant materials of which fermented foods are made. These proteinaceous plant foods have a protein content of 30% to 50% (w/w) (Table 26-17).

As a dietary source of protein, the most important leguminous seeds include cowpea (*Vigna unguiculata*), gram (*Phaseolus* spp.), and pea (*Pisum* spp.). Black and green gram are widely used in Asia, while cowpea is more popular in Africa and the Caribbean. An important source of dietary protein and fat are the various oilseeds of which soya beans (*Glycine max*) are the most important. Whereas soya beans are known and used worldwide, their traditional fermentation processes originate in Southeast Asia. Several types of groundnut (*Arachis hypogaea*) and African oilbean (*Pentaclethra macrophylla*) are used in Asian and African fermented foods. In addition, sunflower seed (*Helianthus* spp.) and agricultural by-products, eg, oilseed presscakes are traditionally converted by fermentation into food materials. The seeds of some trees (*Parkia biglobosa* or locust bean) are gathered and used in traditional fermentations in West Africa.

Range of Types of Fermentation

Three categories of fermented commodities can be distinguished. (1) Products in which extensive hydrolysis and degradation of protein has occurred result in a liquid hydrolysate. These include shoyu and kecap (soya sauces) and are characterized by their high content of soluble nitrogen compounds, particularly free amino acids, which act as flavor enhancers and thus are used as flavorings or condiments. (2) Products in which the integrity of the beans has remained intact have undergone extensive enzymatic modification. The digestibility of their protein has been greatly improved by processing, and a moderate extent of proteolysis contributes to a meat-like flavor. The fermentation of these typical meat-substituting side dishes can be achieved with molds (examples of products are oncom, taoco, miso, tempe) or with bacilli (products including ugba, kinema, itohiki-natto, soumbala, dawadawa, and netetou). (3) Protein-enriched fermented starchy materials, eg, fermentation of rice flour and pea or bean flour, produce Indian idli. The addition of proteinaceous seeds to cereals increases the total protein content, and improves the pattern of amino acids because the lysine deficiency of cereal proteins is compensated by lysine of the legume protein. The protein-enriched cereals undergo a lactic acid fermentation or mixed lactic-alcoholic fermentation. This may entail considerably less proteolysis than in the other two product groups.

Status

Industrialization of fermentation processes is most advanced with Japanese shoyu. In Japan only, the 1989 production was estimated[45] at about 1 to 2 million tons. Soya sauce is also manufactured on an industrial scale in the United States and in Europe. Of the products in the second category, miso is probably produced on the largest industrial scale. Production of industrial and homemade miso in Japan in 1985 was of the order of 600,000 and 60,000 tons, respectively.[29]

Tempe is also consumed in considerable quantities mainly in Indonesia; estimates range from 150,000 to 500,000 tons yearly.[98] Some tempe is produced on small-industrial scale (about 1 ton daily); most tempe, and other products in the second category, are produced on a household scale (10 to 200 kg daily). Category 3 products such as idli are staple foods in India, for example. Industrialization has resulted in the production of packaged, shelf-stable, labor-saving intermediate products such as "instant idli mix" consisting of dried ingredients. Fermentation and finishing of the product still needs to be done in the household.

Composition of Starting Material

Table 26-17 presents overall ranges of approximate composition of leguminous seeds and oilseeds.

Table 26-15 Cyanide in Cassava and Gari

Cassava tubers: *15–500 mg HCN equivalent kg^{-1} fresh weight*
Toxicity: *50–100 mg dose lethal to human adult*
Codex Alimentarius tolerable level in food: *10 mg CN equivalent kg^{-1} dry weight*

	HCN Equivalent mg kg^{-1} Dry Weight

The digestibility of plant protein is often adversely affected by ANFs, which occur naturally in seeds. Processing and fermentation, in particular, can increase the digestibility of proteinaceous seeds.

The epiphytic microflora of dry seeds does not differ significantly from that of dry cereal grains. Predominant microorganisms include several groups of strictly aerobic bacteria and their spores, lactic acid bacteria, some yeasts, and fungal spores.

26.4.2 Fungal Fermentation To Produce Tempe

Method of Production

Tempe is principally a fungal solid-substrate fermented type of food. However, the microbial composition of tempe also includes high numbers of bacteria and yeasts; some of these may influence acceptability and product safety, as will be discussed in the next sections. Although most tempe is made from yellow-seeded soya beans (the product is then called "tempe kedele"), tempe can also be made from various leguminous beans, seeds, cereals, and presscakes (residues of oilpressing from groundnuts, coconut, or other lipid-rich materials). The latter category especially provides a nutritious, yet affordable, food to low-income groups of the population.

To produce tempe, the raw materials are soaked, dehulled, cooked, and then mixed with a starter of sporangiospores, mainly of *Rhizopus oligosporus* (Figure 26-14). The inoculated beans are packed, or wrapped in leaves or plastic sheets with minuscule (approximately 1 mm diameter) perforations. The sporangiospores germinate, and produce profuse mycelium growth, but no sporulation, throughout the substrate, thus "knitting" it together to form a cohesive, sliceable cake. The extent of perforation, the shape and size of the package, and the porosity of the granular product limit the heat and mass transfer to and from the center of the package.

As the actively growing mycelium requires atmospheric oxygen and releases carbon dioxide and heat, these heat and mass transfer limitations affect the availability of oxygen required for growth, the accumulation of CO_2, and the increase in temperature. Traditional manufacturers achieve the desired quality by, for example, adjusting thickness of fermenting beds of raw materials, and reducing the access of air to the material according to the ambient environmental conditions.

Prior to consumption, tempe is heated, eg, in stews, or fried to highly popular "tempe kripik" crunchy chips. Dehydration and grinding yields tempe powder, which can be used to enrich low-protein foods.

The starter used ("usar"; Figure 26-14) for the manufacture of traditional tempe is an interesting example of simple household-scale technology. A rough-surfaced natural carrier is used on which the mold mycelium is grown. Although various plant leaves and even kraft paper can be used, the most popular leaf is that of the "waru" tree (*Hibiscus tileaceus* var. *tileaceus*), which carries microscopically small hairs at the underside, and which does not become too brittle when dried. Some cooked soya beans are inoculated with previous starter, and are sandwiched between two waru leaves (undersides turned inward). When the sandwiches have been incubated for 2 days under humid, warm (30°C) conditions, good mycelial growth and heavy sporulation are visible. At that stage, the sandwiches are opened and kept for a few days exposed in order to sun dry. Packages of usar (the dried leaves with inoculum) are sold in local markets and viability of spores is retained for several months at ambient temperature. The normal epiphytic fungi on waru leaves include typical soil fungi such as *Cladosporium* spp. In Indonesia, the leaves are also heavily loaded with *Rhizopus* and *Mucor* spp. probably because of air dispersion caused by widespread use of fungal fermentations. In the tempe fermentation,

Table 26-16 Fermented Foods Made from Proteinaceous Food Plants

Raw Material	Name and Origin of Fermented Product	Principle of Manufacturing Process	Characteristics and Use of Product	Predominant Microorganisms	References
Category (1): Liquid hydrolysates					
Soya bean (*Glycine max*)	Shoyu (Orient); kecap (Indonesia) soya sauce	Mix autoclaved soya beans and roasted wheat, inoculate with koji starter, solid-state fermentation 2–3 days, followed by brine fermentation (several months), aging, pressing, pasteurization (in Indonesia, no wheat is used).	Liquid hydrolysate; condiment	*Aspergillus oryzae, Tetragenococcus halophila, Zygosaccharomyces rouxii*	1, 75, 126–130
Category (2): Meat-substituting side dishes with a firm consistency of the beans					
African oilbean (*Pentaclethra macrophylla*)	Ugba (West Africa)	Boil seeds 4–5 h, extract and cook cotyledons overnight, cool, wash, soak 6 h, slice kernels, add salt, wrap in leaves, ferment about 5 days.	Condiment	*Bacillus, Staphylococcus, Micrococcus, Leuconostoc* spp.	91, 111
Bambara groundnut (*Voandzeia subterranea*)	Dawadawa-like products	Soak 24 h, dehull, boil cotyledons 15 min., drain, ferment 4 days.	Condiment	*B. subtilis, B. licheniformis*	8
Groundnut (*Arachis hypogaea*)	Oncom (Indonesia)	Soak groundnut presscake, drain, knead with cassava or soya bean residue, steam the dough, press in mold to brick shape, inoculate with dried previous oncom.	Meat substitute	*Neurospora intermedia, N. sitophila*	71, 96
Locust bean (*Parkia biglobosa*)	Soumbala (Mali, Burkina Faso) Dawadawa/Daddawa/Iru (Nigeria) Netetou (Senegal)	Boil beans 12 h, dehull, boil cotyledons again 2 h, drain, ferment 36 h, pound to paste.	Condiment for soups and stews	*Bacillus licheniformis, B. stearothermophilus, B. brevis, B. mycoides, B. subtilis*	5, 107–110
Soya bean (*G. max*)	Taoco (Indonesia) Hama-natto (Japan)	Soak, dehull, boil soya beans, inoculate with tempe starter, ferment 2–5 days, sun dry, ferment in brine 3–4 weeks, cook.	Flavoring agent	*Aspergillus oryzae, Hansenula* spp., *Lactobacillus delbrückii, Rhizopus oligosporus, R. oryzae, Zygosaccharomyces soyae*	74, 81, 152, 162
Soya bean (*G. max*)	Miso (Japan)	Mix crushed, steamed soya beans with salt and mold-fermented rice or barley to paste. Ferment.	Pasty meat extender and seasoning	*Aspergillus oryzae, Saccharomyces rouxii, Tetragenococcus halophila*	46, 152
Soya bean (*G. max*)	Kinema (India, Nepal)	Soak soya beans, cook, crush, dehull, wrap in leaves, ferment 1–3 days.	Condiment; side dish	*B. subtilis, Enterococcus faecium, Candida parapsilosis, Geotrichum candidum*	139–142

Rhizopus and *Mucor* spp. compete successfully with soil fungi because of their faster growth.[104]

In addition to the traditional use of usar, selected pure cultures of *Rhizopus oligosporus* are grown and diluted into soya flour to give defined starter material for tempe fermentations.[154] Whereas small-scale producers prefer usar because of easy availability and handling, industrialization of tempe manufacture will require the development of better-defined starters.

Microbiological and Chemical Changes during Fermentation

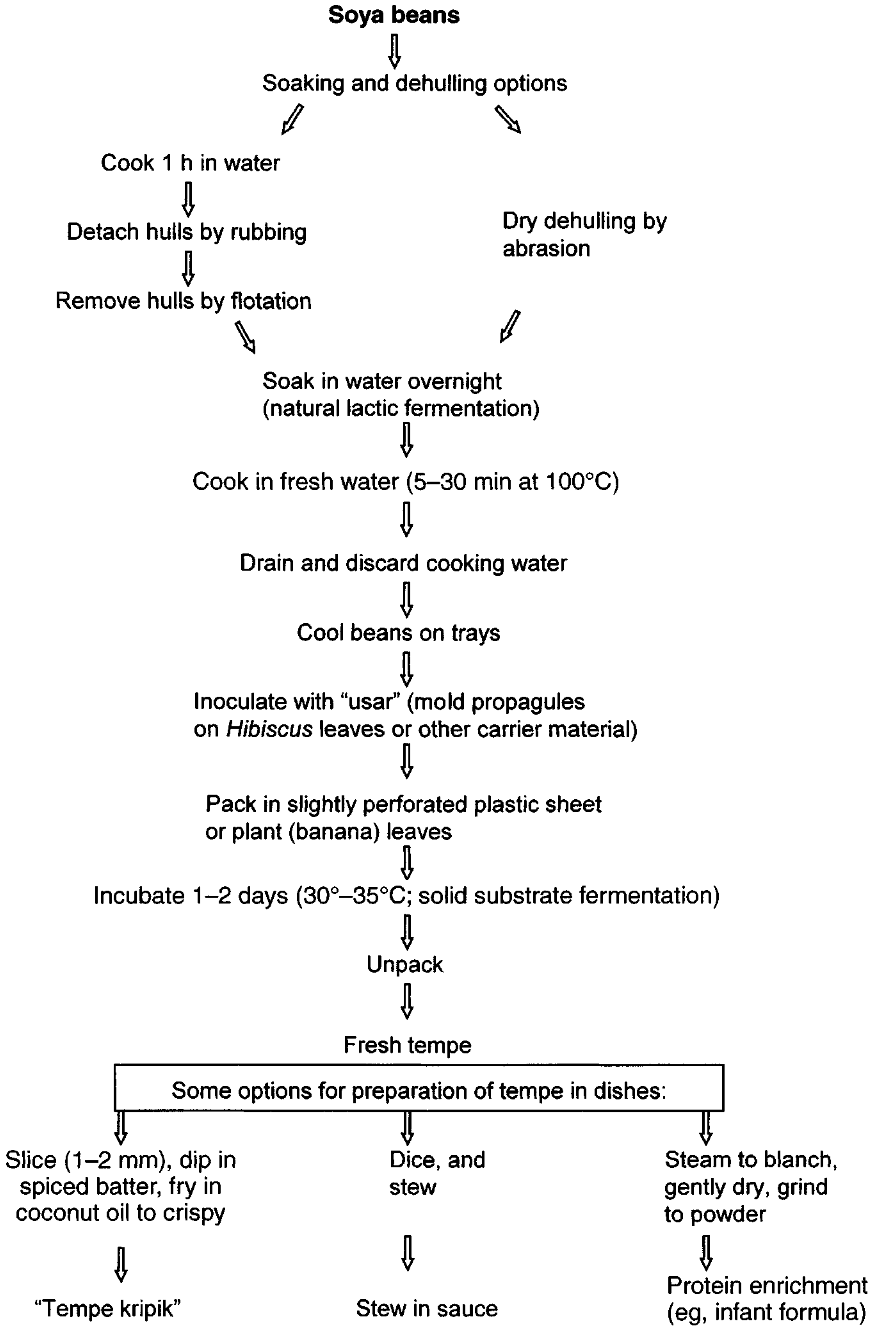
As indicated in the previous section, bacteria and yeasts multiply in tempe during the manufacturing process, and lactic acid bacteria especially play an important role during the first phases of the process. During soaking of the soya beans, fermentable sugars leach into the soak water enabling the growth of acid-producing Gram-positive bacteria (Figure 26-15), including *Lactobacillus casei*, *Staphylococcus epidermidis*, *Enterococcus faecium*, and *Streptococcus dysgalactiae*.

Depending on the soaking conditions, lactic acid bacteria, especially the acid-tolerant species such as *Lactobacillus plantarum*, will dominate the microflora of the soak water either immediately (soak water inoculated) or at the end of the overnight soaking period (succession of naturally occurring microorganisms in the absence of inoculum); Gram-negative bacteria, eg, *Klebsiella pneumoniae*, *Citrobacter diversus*, *Pantoea agglomerans*, *Klebsiella ozaenae*, and *Enterobacter cloacae* are also present in soak water and in tempe. Yeasts, eg, *Pichia burtonii*, *Candida diddensiae*, and *Rhodotorula rubra* were also found in soak water.[86]

Some bacterial acidification of the soak water is desirable because it limits bacterial spoilage during the fungal fermentation stage. Addition of previous soak water as an inoculum results in enrichment of lactic acid bacteria, causes a further decrease in the pH of soya bean soak water (to about 4.5 or 4.0), and lowers the pH of the beans after cooking; potential spoilage and/or food poisoning bacteria are also inhibited. Addition of a pure culture of *Lactobacillus plantarum* at the start of the soaking stage (10^3 cfu ml^{-1} soak water) resulted in tempe with significantly lower counts of Enterobacteriaceae and *Bacillus* spp. ($\log_{10}$ cfu ml^{-1} <1.7) than in tempe obtained from beans that had been soaked without inoculation ($\log_{10}$ cfu ml^{-1} 8.13 and 8.07, respectively).[101]

Tempe making was introduced in the Netherlands by Indonesian immigrants, and the product is manufactured commercially by several small- and medium-scale enterprises. Tempe contains large numbers of bacteria, usually dominated by lactic acid bacteria, but less desirable bacteria are sometimes present in significant numbers (Table 26-18). For instance, in 13% of the samples tested the number of *S. aureus* exceeded 10^5 cfu g^{-1}. *Rhizopus oryzae*, *R. oligosporus*, and *Mucor indicus* are the most important molds. Yeasts may be present at levels of 10^5–10^7 cfu g^{-1}; *Trichosporon* and *Candida* spp. are most frequently encountered.

Fermentation of cooked soya beans to produce tempe (Table 26-19) results in reduction of crude fat, carbohydrates, insoluble fiber, and phytic acid, and in an increase in the levels of a number of vitamins. Additional changes affect the digestibility and nutritive value of the product. During the fermentation, protein nitrogen is enzymatically degraded to small peptides, free amino acids, and amines.[9,55] Soya bean isoflavones (daidzein and glycitein) are hydroxylated[69] or transformed further into 3-hydroxy-



Soya beans
Soaking and dehulling options
Cook 1 h in water
Detach hulls by rubbing
Remove hulls by flotation
Dry dehulling by abrasion
Soak in water overnight (natural lactic fermentation)
Cook in fresh water (5–30 min at 100°C)
Drain and discard cooking water
Cool beans on trays
Inoculate with "usar" (mold propagules on *Hibiscus* leaves or other carrier material)
Pack in slightly perforated plastic sheet or plant (banana) leaves
Incubate 1–2 days (30°–35°C; solid substrate fermentation)
Unpack
Fresh tempe
Some options for preparation of tempe in dishes:
Slice (1–2 mm), dip in spiced batter, fry in coconut oil to crispy
Dice, and stew
Steam to blanch, gently dry, grind to powder
"Tempe kripik"
Stew in sauce
Protein enrichment (eg, infant formula)

anthranilic acid,[31] which has antioxidative properties. These and similar substances have been associated with free radical scavenging and anti-carcinogenic effects.[31]

Raw soya beans contain several ANFs, including phytate (which forms complexes with minerals, protein, and starch), hemagglutinins or lectins (glycoproteins that can bind with intestinal epithelial cells and cause damage to villi), protease inhibitors including trypsin inhibitors, which affect the digestion of protein, and oligosaccharides such as raffinose and stachyose, which cause flatulence and increase stool passage rates, and thus reduce nutrient absorption. Some of these ANFs, such as phytate, are heat-stable

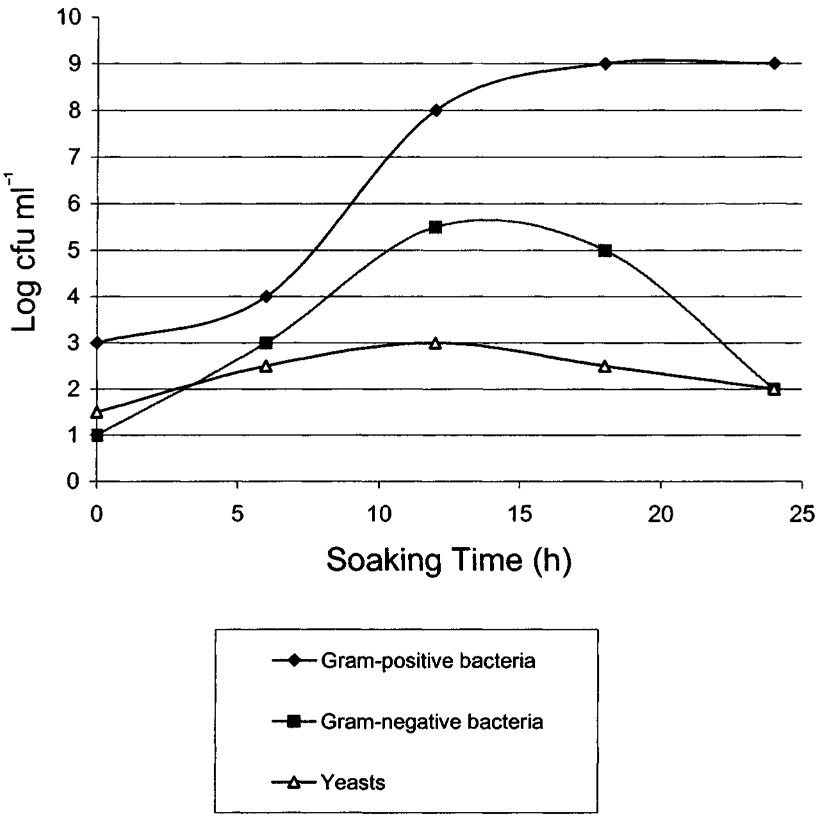

Figure 26-15 Microbiological Changes during Soya Bean Soaking Stage of Tempe Process. *Source:* Data from R.K. Mulyowidarso et al., The Microbial Ecology of Soybean Soaking for Tempe Production, *International Journal of Food Microbiology*, Vol. 8, pp. 35–46, © 1989.

but degradable by fermentation. Others such as Kunitz' trypsin inhibitor, are heat-sensitive but are not easily degraded by fermentation microorganisms.

Processing of soya beans for maximum nutritional benefit should therefore include a combination of treatments, such as grinding, soaking, and cooking (enabling an enzymic degradation prior to heat inactivation), or moistening, cooking, and fermentation.

Prevention of Spoilage

Spoilage during fermentation may occur if beans were not adequately acidified or cooked prior to inoculation. The neutral pH of the cooked beans enables rapid growth of *Bacillus* spp. as well as Enterobactericeae.[100] Poor quality inoculum (ie, poor viability of the mold spores, heavy contamination with other molds and spoilage bacteria) allows outgrowth of undesirable microorganisms.

Table 26-20 gives an indication of the microbial growth in fresh, laboratory-made soya bean tempe when stored at various temperatures. The initial values for total aerobic mesophilic bacteria are considerably lower than those found in commercial tempe (Table 26-18) because these were fresh, and relatively "clean" tempe samples, obtained using pure culture mold starter, using acidified beans, and employing hygienic methods. Such beans have approximately pH 5, and a water activity close to 1.0. Even under such mildly acidic conditions, bacteria in the soaked beans will survive the cooking treatment, and some will be introduced during the subsequent handling of the product. During storage, they will proliferate depending on inhibitory effects such as competition by lactic acid bacteria or inhibition by low temperature, and by acid. The latter effect is counteracted by the pH increase caused by NH_3 formation from protein degradation. This also explains why in commercial tempe sometimes rather high counts of objectionable bacteria are encountered. The product itself is a good growth medium for such bacteria; adequate hygiene and the competition caused by a vigorously active starter of molds and lactic acid bacteria in combination with suitably low storage temperatures are essential for safe storage. Traditionally in Indonesia, fresh tempe is not stored for longer than a few days. In the Netherlands,

Table 26-18 Microbiological Composition of Commercial Tempe Made in the Netherlands (*n* = 110 samples from different producers; production methods not specified)

	Log cfu g^{-1} (in % of all samples)
Aerobic mesophilic bacteria	>7.0 (98)
Enterobacteriaceae	>5.0 (67)

most commercial fresh tempe is wrapped in polyethylene film and kept refrigerated. Under such conditions, the product can be stored for a few weeks before it spoils (turning sour, musty, or smelly). Alternatively, tempe may be pasteurized in a suitable foil package. These pasteurized tempe and derived products (spreads, salads) can be stored refrigerated for several months. No microbiological data are available for these pasteurized products.

Control of Safety

The reduction of pH in the soaking water and the beans caused by the lactic fermentation during the soaking stage tends to inhibit any pathogenic bacteria that may be present. During the subsequent mold fermentation (tempe fermentation) challenge experiments with *Bacillus cereus*,[102] *Staphylococcus aureus*,[103] and *Listeria monocytogenes*[6] indicate that the best protection is offered by the combination of acidified beans (pH approx. 5) and the presence of live lactic acid bacteria in the cooked beans at the moment of inoculation with mold spores. For instance, the addition of *L. plantarum* (7 log cfu ml^{-1} soak water) at the soaking stage prevented growth by 5 log cfu g^{-1} *Bacillus cereus* added to subsequently cooked beans[102]; *L. plantarum* at 7 log cfu g^{-1} cooked beans could not inhibit growth of 3 log cfu g^{-1} *Staphylococcus aureus* but no staphylococcal enterotoxins could be formed[103]; and *L. plantarum* at 3.3 log cfu g^{-1} beans fully inhibited the growth of *Listeria monocytogenes* added at 2.5 log cfu g^{-1} beans.[6] Concluding, lactic acid bacteria not only play a role as flavor makers, but they are important in terms of microbiological safety of the product. It is, however, important that in common practice tempe is either fried or stewed before consumption (Figure 26-14).

26.4.3 Bacterial Alkaline Fermentation To Produce Kinema

An unusual food fermentation is caused by *Bacillus* spp., notably *B. subtilis*, *B. licheniformis*, *B. polymyxa*, and *B. natto* in high protein food plants, forming products such as "dawadawa," "natto," and "kinema." In these "alkaline fermentations" a significant pH increase occurs due to protein degradation. Deamination reactions lead to the formation of volatile amines and ammonia, which cause a pungent odor, and cause the pH to increase from approximately 6.0 in the raw material to 8.5 or even 9.0 in the fermented product.

Method of Production

The traditional process for preparation of kinema is outlined in Figure 26-16. Soya beans are cleaned, washed, soaked, cooked, crushed to form a mass containing the seed hulls, wrapped, and fermented in a warm place until a desirable ammoniacal odor, and a stringy texture has been achieved. Kinema is used as a meat substitute and is fried in oil prior to consumption.

In the traditional process, no starter culture is added. Presumably, *Bacillus* spores survive the cooking and the mass is also "inoculated" by the utensils and wrapping materials used.

Conditions for optimizing the traditional process by control of soaking, cooking, wrapping, and fermentation, and the addition of a starter culture of *Bacillus subtilis* have been suggested[139] but this process is not yet applied on a commercial scale.

Microbiological and Chemical Changes during Fermentation

Of 10 kinema samples collected at market sites all contained (per g wet wt of sample) predominantly *Bacillus subtilis* (8.4–8.7 log cfu) and *Enterococcus faecium* (7.4–8.1 log cfu). Seven samples contained *Candida parapsilosis* (<5.2 log cfu) and four contained *Geotrichum candidum* (<4.9 log cfu).[141] Only the *Bacillus* species were detectable on the raw soya beans; *B. subtilis* grows rapidly at 37° and 45°C in cooked soya beans (Figure 26-17).

E. faecium also grows well at 37°C, but *C. parapsilosis* grows only to a limited extent. When tested individually and in mixed cultures, products fermented by the addition of *B. subtilis* were preferred by a sensory panel to those fermented by combinations of *B. subtilis*, *E. faecium*, *C. parapsilosis*, and *G. candidum* or by *E. faecium* alone.[139]

Table 26-21 shows the approximate composition of soya beans and kinema. Whereas the nitrogen content (approximately 8.5% of dry matter) does not change significantly, proteins are degraded (decrease of protein-nitrogen from approximately 7.5% to 6% of dry matter), causing significant increases of water-soluble-N (from 1% to 5% of dry matter) and non-protein-N (NPN) (from 1% to 2.5% of dry matter). Theoretically, protein-N and NPN should add up to total N, but some protein-N may also be measured as water-soluble-N.

During fermentation, fats (glycerides) are degraded, resulting in a significant increase of free fatty acids (FFA). Part of the released FFA is assimilated by the microorganisms as a source of carbon and energy. Ash content is significantly higher in some samples of kinema; this is explained by the local custom of mixing some wood ash into the product for unknown reasons. The increase of the pH is not always very high; probably it depends on the strains of microorganisms dominating the fermentation, and their ability to produce ammonia.

Inactivation of the antinutritional factors of soya beans, discussed in Section 26.4.2, is important during production of kinema and takes place during the cooking stage.

Table 26-20 Microbial Growth during Storage of Tempe

Log cfu g^{-1}	*Fresh Tempe*	*1 Week 3°–4°C*	*2 Weeks 3°–4°C*	*1 Week 10°C*	*3 Days 21°C*
Total aerobic mesophilic bacteria	5.60	5.60	5.60	7.20	7.90
Bacterial spores	2.11	2.11	2.11	3.80	4.20
Psychrotrophic bacteria[a]	ND[b]	5.62	8.70	ND	ND

[a] Psychrotrophic bacteria were dominated by *Pseudomonas*, Enterobacteriaceae, and enterococci.

[b] ND = Not Determined.

Nout et al., The Influence of Some Process Variables and Storage Conditions on the Quality and Shelf-Life of Soybean Tempeh, *Antonie van Leeuwenhoek*, Vol. 51, pp. 532–534, © 1985.

Prevention of Spoilage

Kinema is preserved usually by dehydration. At the conclusion of the traditional process, the fermented product is sun dried for 1 or 2 days in order to reduce the moisture content to 9% to 12%. During this period, the product darkens considerably due to polyphenoloxidase activity.[141] Other alkaline fermented products, such as dawadawa, are dried in a similar way.[110] By adequate dehydration, the shelf life of kinema and similar products is extended to approximately 1 year.[110,141]

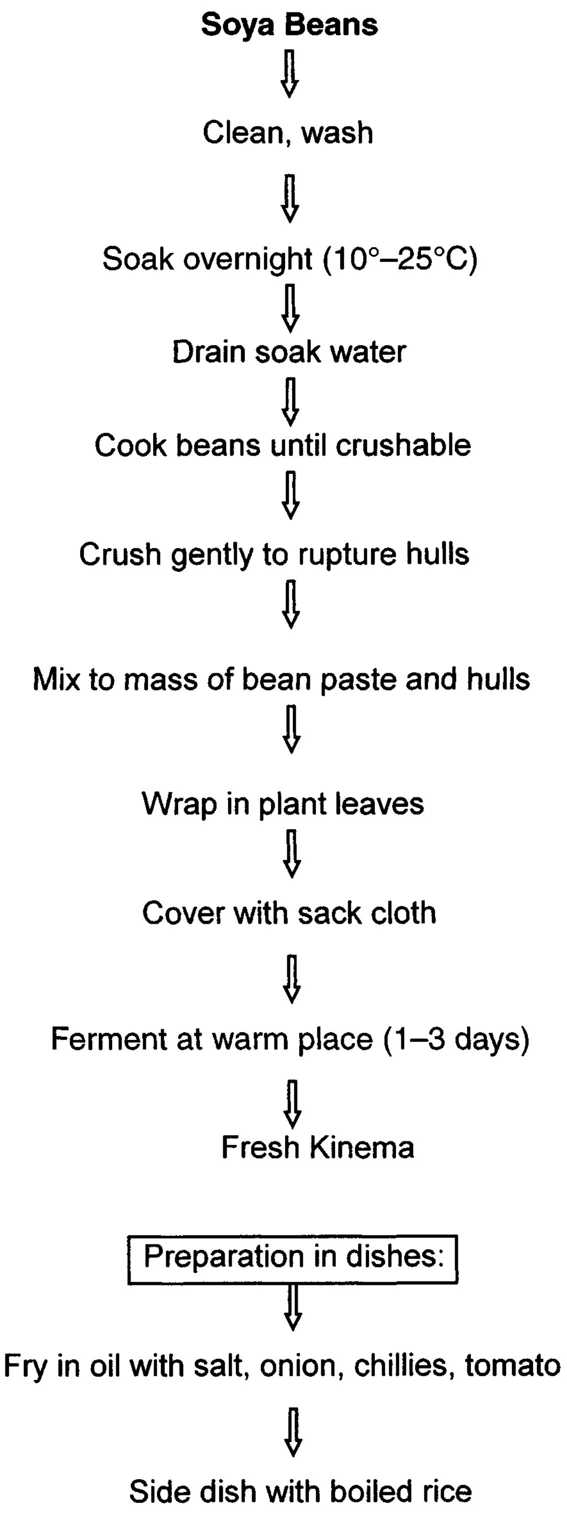
Salt has also been added to dawadawa.[110] NaCl 5% w/w inhibited *B. subtilis* growth and proteolytic activity and enabled the fermentation and enzymatic degradation to be arrested at the desired level.

Control of Safety

Alkaline fermentations are unusual not only for their change of pH, but also for the bacteria involved in the fermentation. *Bacillus subtilis* and *B. licheniformis* are known to be associated with food poisoning (see Chapter 39). At present, no data are available on the ability of the *Bacillus* spp. occurring in alkaline fermented foods, to produce toxins. Considering that these products are traditionally consumed, one might assume that the conditions during production, preparation, and consumption lead to safe products. Presumably, either people who eat kinema, for example, have become resistant to these bacteria, or they are lucky that the predominating strains differ from those causing food poisoning. Alternatively, frying or other preparatory conditions may ensure the safety of this type of product.

Other main concerns are mycotoxins, bacterial pathogens, and toxic metabolites. No published data are available concerning kinema, but some relevant information is available about the similar product dawadawa.

The opportunities for molds to grow on dawadawa during or after the fermentation and sun drying are very limited. *A. flavus* was inoculated on dawadawa, and its aqueous extract, and was unable to grow on both products.[4] Dawadawa itself has a low water activity that may have caused the inability of *A. flavus* to grow on it. However, the inability of *A. flavus* to grow in a watery suspension of dawadawa was overcome after neutralizing its high pH.[110] This would indicate that the risks of aflatoxin accumulation during fermentation or storage are low. On the other hand, no data are available on aflatoxin levels in the raw material or on the effect of the fermentation on aflatoxins. In this type of product, in the presence of



Soya Beans
Clean, wash
Soak overnight (10°–25°C)
Drain soak water
Cook beans until crushable
Crush gently to rupture hulls
Mix to mass of bean paste and hulls
Wrap in plant leaves
Cover with sack cloth
Ferment at warm place (1–3 days)
Fresh Kinema
Preparation in dishes:
Fry in oil with salt, onion, chillies, tomato
Side dish with boiled rice

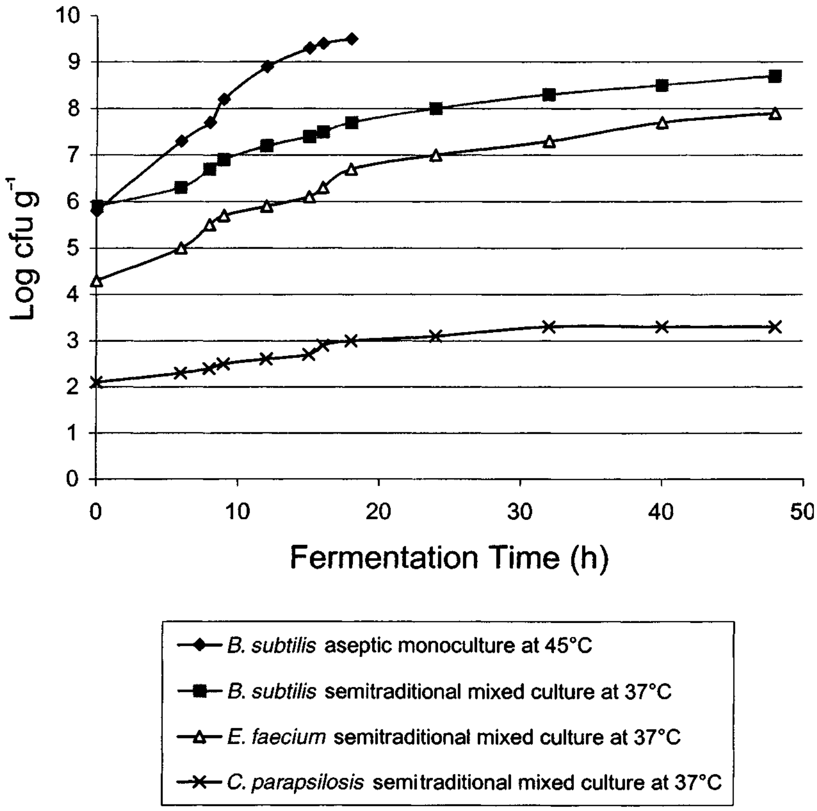

Figure 26-17 Microbial Growth in Semitraditional Mixed Culture Kinema (37°C) and Kinema Produced under Aseptic Conditions with a Monoculture of *B. subtilis* (45°C) (log cfu g^{-1}). *Source:* Reprinted with permission from P.K. Sarkar and J.P. Tamang, Changes in the Microbial Profile and Proximate Composition during Natural and Controlled Fermentations of Soybeans To Produce Kinema, *Food Microbiology,* Vol. 12, pp. 317–325, © 1995, Academic Press Ltd.

significant levels of ammonia, part of the aflatoxins that may be present would probably be degraded, as was demonstrated in ammonia-treated maize.[163] No data are available about other mycotoxins.

There appear to be no published studies of the incidence of human pathogenic bacteria in kinema and similar products. The bacterial hygiene and safety of African alkaline fermented foods have been termed questionable[156]; however, the reduced water activity and the salt in this type of product would inhibit *Clostridium* and *Salmonella* spp.[110] Pertinent data will be needed on bacterial quality of commercial samples, and on the limitation of growth and toxin production by the product.

Another area of concern is the formation of biogenic amines including tyramine, histamine, putrescine, and cadaverine.[156] Studies of the concentrations of these compounds in kinema and similar products have not been made. The presence of high levels of precursor amino acids increases the chance of biogenic amine formation if decarboxylase-active bacteria are present. The safety of alkaline fermented proteinaceous foods could certainly be improved by using starter cultures that have been selected on criteria including nonpathogenicity and inability to decarboxylate amino acids.

26.4.4 Mixed Fungal, Bacterial, and Yeast Fermentation To Produce Soya Sauce

Method of Production

Soya sauces are of Oriental origin; a wide range of products and processes has been described to produce these flavorings.[45] Generally, Japanese soya sauces ("shoyu") are made of a mixture of equal weights of wheat and yellow-skinned soya beans. However, in Indonesia, soya sauce ("kecap") is made of black-skinned soya beans only. Figure 26-18 outlines the principle of a process for Japanese koikuchi-shoyu, one of the most popular types. Autoclaved soya beans and roasted and crushed wheat are blended and inoculated with a defined starter of *Aspergillus sojae*

Table 26-21 Approximate Composition of Market Samples of Kinema and of Soya Beans

	Soya Beans	*Kinema*
Moisture % w/w	9.5–12.0	57.3–64.8
Crude protein % w/w dm[a]	45.8–48.2	45.8–49.2
Crude fat % w/w dm	20.3–24.0	14.4–19.2
Carbohydrates % (by difference)	22.6–29.4	23.4–33.7
Ash % w/w dm	4.5–5.2	5.8–8.4
pH	6.60–6.85	6.95–8.50
TTA % w/w as lactic	0.01	0.06–0.12
FFA % w/w as linoleic	0.04–0.15	2.1–3.3
Energy MJ/100 g dm	2.0–2.3	1.8–2.1

[a] dm = dry matter.

and *A. oryzae* conidia. The resulting mass is incubated for several days at 25° to 30°C to undergo a solid-substrate fermentation. The resulting product is called "koji" (in Indonesia: "bungkil").

The second phase of the process is a liquid fermentation of the koji in a brine at 16% to 19% w/v NaCl. This stage of liquid fermentation is known under the names "moromi" (Japan) and "baceman" (Indonesia). The fermentation, traditionally carried out at approximately 25° to 30°C, takes several months to complete. During this period, soya beans are solubilized into a hydrolysate and fermentation by halotolerant lactic acid bacteria (*Tetragenococcus halophila*) and osmotolerant yeasts (*Zygosaccharomyces rouxii* and *Candida* spp.) takes place.

The final phase of the process involves filtration of the liquid hydrolysate, bottling, and pasteurization. In Indonesia, sweetened types of kecap are made by adding palm or cane sugar and various herbs and spices to the crude kecap.

Microbiological and Chemical Changes during Fermentation

The Initial Fungal Fermentation Stage. *Aspergillus oryzae* and *A. sojae* are considered to be biovars of *Aspergillus flavus*. Raw materials (soaked and cooked soya beans, either alone or mixed with steamed rice, or with roasted and crushed wheat or barley) are inoculated with about 1% of conidial starter and spread in thin (2 to 5 cm) layers on trays. Some large-scale enterprises for soya sauce production have mechanized this solid-substrate fermentation using reactors with forced ventilation and intermittent agitation. The fungal growth takes a few days at 25° to 30°C and is aimed at maximizing the activity of proteolytic, saccharolytic, and other enzymes in the fermented mass. The koji is usually harvested when spore pigmentation starts.

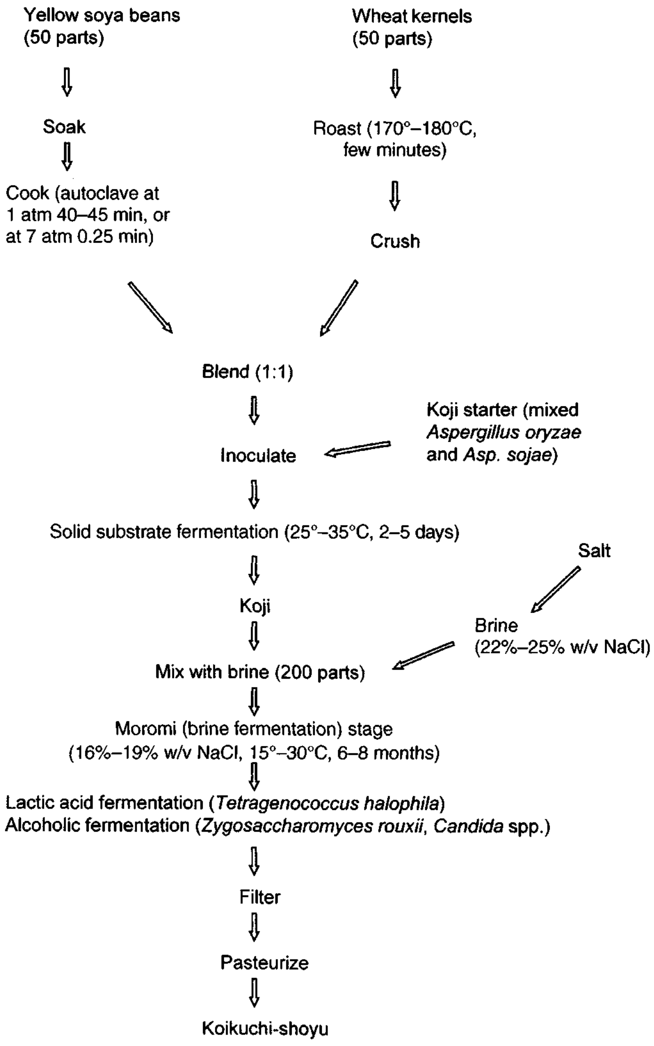
The solid-substrate fermentation (SSF) takes several days; during this period active mycelial growth and sporulation take place. During this period, *Aspergillus oryzae* and *A. sojae* consume 15% to 30% of the carbohydrates of the blend. Also, CO_2 and heat are produced, and the moisture content of the blend (koji) decreases to 20% to 25%. Most importantly, a variety of proteolytic, saccharolytic, lipolytic enzymes as well as phosphatases and other enzymes are produced. The production, stability, and activity of these enzymes are influenced by the temperature, pH, and water activity of their environment.

The Brine Fermentation Stage. The next step is a submerged fermentation. The salt solution is mixed with the koji and the resulting suspension (moromi) has 16% to 19% w/v NaCl. This suspension will be aged for 6 to 12 months, and during this period a gradual degradation of the macromolecular substrate will take place, caused by the fungal enzymes in the koji. Polysaccharides are degraded into oligo- and monosaccharides, proteins into peptides and free amino acids, and lipids into glycerol and free fatty acids. The salt concentration is crucial and is adjusted depending on the prevailing temperatures. In principle, the salt concentration must be increased at higher temperatures in order to avoid microbial spoilage. Low concentrations of salt will allow rapid enzymatic degradation of substrate, but they will also enable extensive (undesirable) microbial growth. Higher salt concentrations inhibit the activity of lactic acid bacteria (as evidenced by slower pH decrease and inhibition of flavor production) and slow down the enzymatic degradation process, but increase safety from microbial pathogens and toxigenic microorganisms.

During traditional brine fermentation in Japanese soya sauce, a natural succession of halotolerant lactic acid bacteria (*Tetragenococcus halophila*, formerly known as *Pediococcus halophilus*) and osmotolerant yeasts (*Candida* spp. in Indonesian kecap; *Zygosaccharomyces rouxii* in Japanese shoyu) will take place without any inoculation.

In Indonesian soya sauce, the situation may be somewhat different. Figure 26-19 shows that the development of lactic acid bacteria and yeasts is rather simultaneous and the latter are numerically dominated by the lactic acid bacteria. In the situation cited in Figure 26-19, *Zygosaccharomyces rouxii* was not detected.

In larger-scale industrial settings with strict management of hygiene, natural inoculation may not be



Yellow soya beans
(50 parts)
Wheat kernels
(50 parts)
Soak
Roast (170°–180°C, few minutes)
Cook (autoclave at 1 atm 40–45 min, or at 7 atm 0.25 min)
Crush
Blend (1:1)
Koji starter (mixed *Aspergillus oryzae* and *Asp. sojae*)
Inoculate
Solid substrate fermentation (25°–35°C, 2–5 days)
Salt
Koji
Brine (22%–25% w/v NaCl)
Mix with brine (200 parts)
Moromi (brine fermentation) stage
(16%–19% w/v NaCl, 15°–30°C, 6–8 months)
Lactic acid fermentation (*Tetragenococcus halophila*)
Alcoholic fermentation (*Zygosaccharomyces rouxii*, *Candida* spp.)
Filter
Pasteurize
Koikuchi-shoyu

Figure 26-18 Principle of the Production Scheme of Japanese-Style Soya Sauce (Koikuchi-Shoyu). *Source:* Reprinted with permission from D. Fukushima, Industrialization of Fermented Soy Sauce Production Centering around Japanese Shoyu, in *Industrialization of Indigenous Fermented Foods,* K.H. Steinkraus, ed., pp. 1–88, © 1989, by courtesy of Marcel Dekker, Inc.

sufficient to achieve the desired lactic and alcoholic fermentation. Industrial soya sauce fermentations are therefore inoculated at the required moment with separately grown pure cultures of lactic acid bacteria and yeasts. *T. halophila* is added first to the moromi mash and this is kept at 15°C for 1 month allowing the pH to decrease from 6.5 to 5.0. At this stage, *Z. rouxii* and *Candida* spp. are added, and the temperature is allowed to rise gradually to 28°C during a 4-month period enabling an active alcoholic fermentation.[75] As a result, 2% to 3% ethanol and other metabolites are produced, such as higher (C_{3-5}) alcohols and glycerol. Organoleptic properties are associated in part with levels of alcohol, salt, reducing sugar, color, soluble nitrogen, glutamic acid, titratable acid, and pH. More than 300 compounds have been identified in soya sauce, many of which may contribute to the flavor of the product.

Prevention of Spoilage

Particularly during the brine fermentation stage, the control of pH, dissolved oxygen, and salt concentration is important. During the early part (first 6 days) of the brine fermentation halotolerant lactic acid bacteria reduce the pH and concentration of dissolved oxygen, and the resulting conditions prevent the growth of aerobic spoilage microflora. In Indonesian kecap, such aerobic microorganisms were mainly coryneform bacteria. If aerobic spoilage does occur it takes the form of pellicle formation, and is often associated with the formation of off-odors caused by oxidation.[128]

In later stages of the process (after 6 days of brine fermentation), the combination of low levels of dissolved oxygen, pH <5.4, and NaCl concentration >10% w/v is associated with low levels of corynebacteria and absence of pellicle formation, and facilitates product stability. Long-term shelf life of soya sauce is achieved usually by bottling and pasteurization, and is limited by chemical and sensory changes rather than by microbiological changes. The slightly acidic pH (4.6–4.8), the presence of weak organic acids (mainly lactic, pyroglutamic, acetic, succinic, citric, and formic acids, totaling approx. 1.3% w/v), and considerable NaCl concentrations (16.9% to 19.0% w/v)[45] all contribute to the microbiological stability of the bottled and pasteurized product.

Control of Safety

A. oryzae is regarded as a variety of *Aspergillus flavus*, but, in contrast with *A. flavus*, *A. oryzae* has not been found to produce the highly toxic and carcinogenic aflatoxins. No aflatoxins could be produced by industrial soya sauce starters, and no aflatoxins have ever been found in Japanese soya sauce.[45] In Korean soya sauce, aflatoxins were chemically unstable.[118]

Yeast metabolism of citrulline may lead to the accumulation of carbamic acid, which in turn may react with ethanol to form ethylcarbamate (urethane). The latter compound is toxic, and has been found in several yeast-fermented products, including soya sauce. The levels varied from nondetectable to 35 ppb with a mean of 17.7 ppb; a "no significant risk" level of 0.7 μg day^{-1} has been reported.[80] In view of the widespread daily use of soya sauce in Eastern Asia, process control measures to minimize ethyl carbamate levels will be desirable.

Recently, mutagenic effects of soya sauce were observed using Ames tests.[54] At present, it is not known which substances cause these effects, and whether they are active in human tissue as well.

26.5 CONCLUDING REMARKS

Fermented foods based on vegetables, cereals, and proteinaceous seeds play an important role worldwide, and will continue to do so. The ever-increasing world population will require more affordable nutrients and energy presented in a palatable and safe manner. Fermentation is of interest for reasons of sensory appeal, nutritional and physiological effects in the consumer, and of product safety. However, several cases of foodborne infections and intoxications have been associated with fermented foods.[95] Considering the contamination of food raw materials, the high levels of water activity, nutrients, and pH in some fermented foods, and occasional inadequate processing and storage conditions, a few major risk factors can be identified: (1) the use of previously contaminated raw materials (eg, with mycotoxins, heavy metals, and other stable compounds); (2) lack of pasteurization (such as occurs in some cheese and vegetable products); (3) the use of poorly controlled natural fermentations, or of inadequate fermentation starter cultures (thus providing ineffective substrate colonization, and enabling opportunistic microorganisms to develop); (4) inadequate storage or maturation conditions enabling survival of pathogens, or growth and toxin production (eg, insufficient levels of curing salts; inadequate protection from air exposure); and (5) consumption without prior heating (thus allowing the product to act as a vehicle for foodborne infections, for example).

The study of processes and microbiological and chemical changes taking place during traditional fermentation processes provides the basic data to investigate aspects of safety and nutrition. At the industrial level, but also in the household, consumer safety is a first priority. From a commercial point of

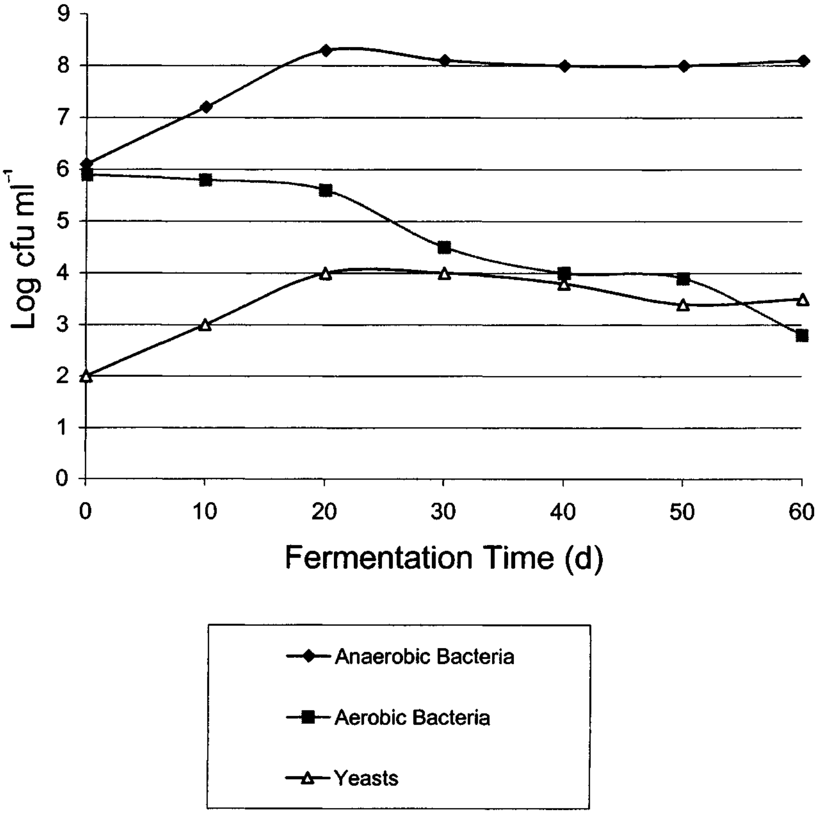


Figure 26-19 Microbiological Changes during the Liquid Fermentation Stage ("baceman" with 15% w/v NaCl concentration) of Indonesian Soya Sauce Fermentation. Anaerobic bacteria: progressively *Tetragenococcus halophila*; aerobic bacteria: coryneform bacteria; yeasts: *Candida* spp. (*C. parapsilosis, C. famata, C. guilliermondii, C. pulcherrima*). *Source:* Data from W.F.M. Röling et al., Changes in Microflora and Biochemical Composition during the Baceman Stage of Traditional Indonesian Kecap (Soy Sauce) Production, *J. Ferm. Bioeng.*, Vol. 77, pp. 62–70, © 1994.

view, control of processes is essential, based on a thorough understanding of the fundamentals.

Future developments are likely to include (1) optimization of fermentation practices to meet food safety requirements, and (2) increased use of (safe) defined cultures of microorganisms and of enzymes that have been tailor-made by molecular-biological techniques. This practice will be especially interesting to achieve effects that cannot be realized with conventional ingredients. For instance, traditional fermented foods (well known and popularly accepted) are increasingly used as a vehicle for the use of probiotic microorganisms. Probiotic fermented dairy products[122] are available commercially; probiotic fermented cereal soups[77] are actively investigated.

From a processing point of view, large-scale industrial manufacture of Japanese soya sauce may provide an indication of what is possible in terms of continuous processes using immobilized microorganisms, membrane filters, solid-substrate bioreactors, and others.[75] Considering the increasing world population, industrialization of (fermented) food manufacture is bound to expand; however, one has to realize that at present, a significant segment of the population derives income from the artisanal processing of foods.

27 Fresh and Processed Fruits

Barbara M. Lund and Anna L. Snowdon

CHAPTER CONTENTS

27.1 Introduction
27.2 Composition and properties
27.3 Major groups of microorganisms associated with fresh fruits
27.4 Microbiological spoilage of fresh fruits
27.5 Microbiological safety of fresh fruits
27.6 Control of microbiological spoilage of fresh fruits
  27.6.1 Preharvest measures
  27.6.2 Harvesting and handling techniques
  27.6.3 Postharvest treatments
  27.6.4 Cooling
  27.6.5 Storage
  27.6.6 Packaging
27.7 Control of microbiological safety of fresh fruits
  27.7.1 General principles
  27.7.2 Treatment of fruits with antimicrobial agents to inactivate pathogenic organisms
27.8 Frozen fruits
  27.8.1 Processing and its effect on microorganisms
  27.8.2 Control of microbiological safety and quality of frozen fruits
27.9 Dried fruits
  27.9.1 Processing and its effect on microorganisms
  27.9.2 Control of microbiological spoilage and safety of dried fruits
27.10 Canned fruits
  27.10.1 Processing and its effect on microorganisms
  27.10.2 Control of microbiological spoilage and safety of canned fruits
27.11 Concluding remarks
References

27.1 INTRODUCTION

A fruit is defined strictly as the seed-bearing product of a flowering plant (tree, bush, or herb), and is derived from transformation of the ovary or associated tissue. This definition includes cereals, pulses, nuts, and spice fruits, as well as the fleshy fruits, which are considered in this chapter. The definition of fruits includes tomatoes, peppers, cucumbers, and other cucurbits, regarded as vegetables in the culinary context.

The world production figures for fruits (Table 27-1) indicate the relative importance of different fruits; grapes are of major importance but are used mainly to produce wines.

Fruits are classified commonly into temperate zone, subtropical, and tropical products.[59] Temperate zone fruits include pome fruits (eg, apple and pear); stone fruits (eg, apricot, cherry, nectarine, peach, and plum); and soft fruits (eg, grape, strawberry, raspberry, and cranberry). Subtropical fruits include citrus fruits (eg, orange, lemon, and grapefruit), and noncitrus fruits (eg, avocado, fig, and kiwifruit). Tropical fruits include banana, mango, papaya, pineapple, and a range of minor fruits.

The source of these fruits determines the type of plant pathogen that causes disease during growth and that also may cause postharvest spoilage. The growing conditions of fruits also influence the microbial flora on the product and the incidence of human pathogenic microorganisms, which may survive during harvesting and retail sale and cause outbreaks of disease.

27.2 COMPOSITION AND PROPERTIES

The majority of fruits contain between 10% and 25% of carbohydrates, less than 1% of protein, and less than 0.5% fat. Avocados and olives are exceptional in that they contain a relatively high concen-

tration of fat, between 3% and 30% in avocados and up to 20% in olives.[65] The carbohydrate content of fruits includes cellulose, hemicellulose, lignin, and pectic substances, all of which contribute to the dietary fiber in the human diet. Most fruits are relatively acidic; acids can account for up to 2% to 3% of the total fresh weight of fruits such as lemons and limes. The major acids present in many fruits are malic and citric, but tartaric acid is abundant in most cultivars of grapes, and quinic acid is important in some fruits such as plum, cherry, and kiwifruit. The concentration of acid and the pH in fruit are influenced by the cultivar, the soil conditions, and the maturity of the fruit.[109] Examples of pH values are shown in Table 27-2.

Fresh fruits are an important source of dietary vitamins, particularly vitamins C and A, and of minerals including magnesium, iron, potassium, phosphorus, and calcium.[59]

Fruits can be divided into two groups: climacteric and nonclimacteric. These groups show differences in their pattern of respiration and in their ability to ripen after harvest.[59,63,133]

Table 27-2 Approximate pH and Main Organic Acids of Selected Fruits

Fruit	*pH*	*Main Organic Acids*
Lemon[a]	2.2–2.4	citric
Cranberry[a]	2.5–2.7	citric, malic, quinic
Passionfruit[a]	2.6–3.3	citric, malic
Plum[a]	2.8–4.6	malic, quinic
Grapefruit[a]	2.9–3.4	citric
Grape[a,e]	3.0–4.5	tartaric, malic
Orange[a]	3.0–4.0	citric, malic
Kiwifruit[b]	3.1–4.0	citric, malic, quinic
Peach[a]	3.1–4.2	malic, citric
Cherry[a]	3.2–4.7	malic, quinic, citric, isocitric
Pineapple[a]	3.2–4.0	citric, malic
Strawberry[c,d]	3.3–3.6	citric, malic
Apple[a]	3.3–4.1	malic, citric, lactic
Mango[a]	3.3–3.7	citric, tartaric
Pear[a]	3.4–4.7	malic, citric, quinic
Tomato, under-ripe[e]	3.2–4.5	
Tomato, ripe[e]	3.4–4.7	
Tomato, over-ripe[e]	4.0–4.8	
Banana[a]	4.5–5.2	citric, malic, tartaric
Papaya[a]	4.5–6.0	citric, malic, ketoglutaric
Watermelon[a]	5.8–6.0	citric, malic
Melon, cantaloupe[a]	6.2–6.5	citric, malic
Melon, honeydew[a]	6.3–6.7

Climacteric fruits undergo a sudden surge in their respiration rate, which is associated with ripening, usually after harvest. This increased respiration is triggered by ethylene that is produced by the fruit itself. Because of this response to ethylene, climacteric fruits can be harvested when mature but unripe, and can be ripened off the plant after harvest by ethylene produced by the fruit or by the controlled application of ethylene. Climacteric fruits include tomato, banana, apple, pear, peach, plum, avocado, and kiwifruit.

Nonclimacteric fruits produce very little ethylene and their rate of respiration remains constant (at constant temperature) and may fall slightly after harvest. These fruits do not ripen in response to treatment with ethylene, except that degreening (degradation of chlorophyll) takes place in some fruits. These fruits do not continue the ripening process after removal from the plant, and must be ripened on the plant before harvest. Nonclimacteric fruits include citrus, grape, pineapple, strawberry, cherry, olive, pepper, and cucumber.

The compositional changes that occur during ripening have a marked effect on the susceptibility of fruits to physical damage and to microbial spoilage. During ripening starch is converted into sugars, principally sucrose, glucose, and fructose; the total concentration of sugars can be about 8% in juice of apples, 20% in juice of grapes, and 4% in juice of strawberries.[59] Polysaccharides such as cellulose, hemicellulose, pectin, and lignin, which are present mainly in the cell wall, are broken down into smaller molecular weight, soluble compounds, resulting in softening of the tissue. The acid content of fruits tends to decrease and the pH to increase during ripening because of utilization of organic acids during respiration or their conversion into sugars. As fruits ripen, the characteristic skin color, flavor, and aroma develop and the fruit reaches its stage of prime eating quality or "ripeness." Subsequently, as the rate of respiration declines, senescence sets in, off-flavors develop, and the dying tissues become increasingly susceptible to microbial spoilage.

27.3 MAJOR GROUPS OF MICROORGANISMS ASSOCIATED WITH FRESH FRUITS

As the flower bud develops into a flower and eventually into a mature fruit the surfaces are colonized by a succession of microorganisms. Many of these microbes originate from the soil and may be spread by wind or rain, or transported by insects. The majority of microbes remain on the surface of fruits; occasionally microorganisms, particularly fungi, invade the fruit while it is still on the plant, and the fruit may then rot, lose moisture, and become "mummified." The mummified fruits may remain attached to the plant or fall to the ground, but in either case they tend to give rise to large numbers of fungal spores, which may be disseminated by wind, water, and insects. In suitable weather conditions, infection of grapes with *Botrytis cinerea* results in mummification of the fruits on the vine; the fruits become dried, concentrating sugars and glycerol ("Noble rot"), and these fruits are used to make certain sweet wines.[94]

Low numbers of bacteria have been reported within some fruits and vegetables, in particular tomatoes and cucumbers.[71,97] In tomatoes, the bacteria were found most frequently in the stem scar and central core, and there was evidence that the bacteria entered the fruit in the vicinity of the sepals; this was linked with the use of overhead irrigation.[96] In cucumbers, the bacteria were more abundant in the periphery than in the central axis, suggesting that they may have entered through stomates or broken hairs.[97]

Molds are important contaminants of fruit surfaces but assessment in terms of numbers present is complicated by the presence of extensive mycelia and of fruiting structures containing large numbers of spores. High numbers of yeasts are often present but there are few data on the numbers of bacteria present. Up to 7.8 × 10^5 yeasts g^{-1} on sound, mature apples and up to 1.4 × 10^6 g^{-1} on grapes were reported by Davenport,[25] and counts of 10^3–10^4 yeasts g^{-1} on apples, and 10^7 yeasts g^{-1} on grapes were reported by Splittstoesser.[109] On freshly harvested soft fruit (strawberries, raspberries, and blackberries), the number of yeasts was between 10^4 and 10^6 g^{-1}, that of molds was up to 10^4 g^{-1}, and the number of bacteria was between 10^5 and 10^6 g^{-1}.[28] Fruit that has been damaged by birds, insects, or pathogenic fungi is liable to contain high numbers of yeasts that are able to multiply on the damaged fruit tissue. The numbers of lactic acid bacteria on fruit as received from orchards and vineyards is usually very low.[109] In a study of sound grapes, about 50% of samples were contaminated with acetic acid bacteria in numbers of 10–10^4 g^{-1}; all the strains isolated were *Gluconobacter suboxydans*.[110]

The numbers and types of microorganisms present on freshly harvested fruit will depend on the weather, the season, the time of harvest within a season, the type of fruit and its proximity to the ground, irrigation, and preharvest treatment with chemicals such as fungicides.

Where bacteria pathogenic to humans are present on fruits, this is predominantly a result of contamination from animals and humans. Wild animals and birds can be a source of contamination but information on outbreaks of disease in humans associated with the consumption of fruits and fruit products indicates that contamination has often resulted from exposure of fruit to human or animal waste or to irrigation water or other water that has been contaminated from these sources.

27.4 MICROBIOLOGICAL SPOILAGE OF FRESH FRUITS

Postharvest spoilage of fresh fruits is often caused by plant-pathogenic microorganisms that cause disease in the field. Some disease organisms cause local disfigurement in the form of discrete ***spots, cankers,*** or ***scabs,*** which may develop no further after harvest. More often, however, the fruit is harvested in apparently good condition, and subsequent deterioration, once started, tends to be progressive. The same organism can cause a ***dry rot*** under conditions of moderate humidity or a ***wet rot*** under conditions of high humidity. The term "mildew" is sometimes used loosely to describe any superficial mold growth. Strictly speaking, ***downy mildews*** are caused by fungi of the family Peronosporaceae, while ***powdery mildews*** are caused by fungi belonging to the Erysiphaceae. ***Anthracnose*** means "coal-like," and was first used to describe a disease of grapes in which blackening of the tissues was a striking feature. It is now used for a group of diseases, characterized by black lesions that become covered with pink spore masses. The causal fungi are certain species in the order Melanconiales.

The major causes of postharvest spoilage (postharvest disease) in fruits are shown Table 27-3. The main spoilage organisms of a given fruit may be very dependent on the growing area.

Postharvest spoilage can occur as a result of infection in the field. For example, branches of mango trees may be permeated by endophytic mycelium of *Dothiorella dominicana,* which subsequently can result in a postharvest stem-end rot of the fruit.[57] Other microorganisms may remain on the surface of the fruit, fungal spores may germinate but the organism may fail to penetrate the fruit, or penetration into the fruit may occur but the organism may fail to progress into the tissue (remain quiescent) for a period of time, often until ripening occurs.[88] Some

fungi, for example *Colletotrichum gloeosporioides*, which causes major spoilage of tropical fruits, are able to penetrate the intact cuticle of leaves, stems, and fruits. Following germination of the mold spore on the plant surface, a swelling (appressorium) is formed on the underside of the spore and from this appressorium a thin strand grows through the cuticle and into or between plant cells.[117] *Botrytis cinerea* can penetrate the flower parts, including petals, stigmas, styles, or stamens, of fruit such as strawberries, raspberries, and grapes. However, it may remain quiescent until conditions are favorable for it to resume growth and invade the fruit, often later in the growing season, during ripening or after harvest. The extent of preharvest fungal colonization is considered to be a primary determinant of postharvest decay of cherries.[33]

Other spoilage organisms enter the fruit mainly through mechanical injuries or through natural openings such as lenticels. Examples are *Penicillium expansum*, which is a major cause of spoilage of pome fruits and stone fruits, and *Erwinia carotovora*, an important cause of postharvest spoilage of field-grown tomatoes and of peppers. Spoilage of fruits is often initiated after harvest. Physical damage during harvesting and handling and exposure to stress conditions increase the susceptibility of the fruit. Consequently, microorganisms that have remained on the surface of the fruit are able to gain access to and attack the inner tissue. The ability of microorganisms to break down the tissue of fruits and to cause rots is associated with their ability to form cell wall–degrading enzymes, in particular, pectic enzymes.[22]

In many conditions the development of microorganisms in plant tissues is prevented by factors such as preformed inhibitors or inhibitors that are formed in response to injury or infection. Ripening is accompanied by weakening of cell walls and a decline in the ability of the fruit to produce antifungal substances. Susceptibility of the fruit to spoilage organisms generally increases and factors such as damage during harvesting and handling, and maintenance of the fruit in conditions of high humidity and high temperature, favor the development of spoilage.

27.5 MICROBIOLOGICAL SAFETY OF FRESH FRUITS

For many years travelers in various parts of the world have been aware of the risk of contracting disease as a result of the consumption of fresh fruits and other produce. Reports of the incidence of human pathogenic bacteria on fresh fruit have been summarized by Beuchat.[5] The proportion of outbreaks and cases of food poisoning associated with the consumption of fruits that are investigated and reported is probably low, but surveillance in the United States (US) indicates that the proportion of foodborne outbreaks that are associated with fresh produce has increased in recent years.[119] Factors that have contributed to this perceived increase may include improved reporting, larger and more centralized production and longer food chains, and an increase in global trade.[119] Examples of reported outbreaks of foodborne disease associated with contamination of fresh fruit are shown in Table 27-4.

Contamination of apples with manure from grazing cattle was probably the cause of outbreaks of infection with *Salmonella, Escherichia coli* O157, and *Cryptosporidium parvum* associated with unpasteurized apple juice. The use of oranges that have fallen to the ground, where they have been contaminated with *Salmonella,* and have then been processed without adequate washing was suspected as the cause of infection associated with unpasteurized orange juice (Table 27-4).[119] Contamination of raspberries before harvest may have contributed to an outbreak of infection with *Cyclospora* in 1996.[119] Pickers were suspected as the cause of contamination of raspberries in an outbreak of hepatitis A infection in Scotland in 1983.[92]

The pH of many fruits is lower than 4.0 and this low pH, combined with the presence of organic

acids, generally prevents the multiplication of foodborne pathogenic bacteria. Nevertheless, these bacteria may survive for a sufficient time to cause foodborne disease. The pH of cantaloupe and honeydew melons is in the region of 6.2–6.7 and that of watermelons is between 5.8 and 6.0. If these melons are sold as cut pieces any foodborne pathogens that are present may multiply on the cut surfaces of these and other fruits with a similar pH. *Salmonella* spp. and *Shigella* spp. have been shown to multiply on the cut surface of watermelons, cantaloupes, honeydew melons, papaya, and jacima fruits at 23° to 27°C.[34,40,41] *Salmonella* spp. have also been reported to multiply at 22°C on the cut surface of tomatoes with a pH between 3.99 and 4.37,[1] and *Salmonella montevideo* survived better at the stem scar and in growth cracks on tomato skin, and multiplied on puncture wounds and on tomato slices at 25°C.[129] *Escherichia coli* O157:H7 multiplied on cubes of cantaloupe and watermelon at 25°C and on the rind surface at 25°C and high humidity.[27] *Campylobacter jejuni* was reported to survive on sliced watermelon and papaya for sufficient time to present a risk to the consumer.[11] Initiation of bacterial soft rot may result in conditions that favor survival and growth of *Salmonella* in fruit.[130]

Strains of some species of mold including *Penicillium, Aspergillus,* and *Fusarium,* which may be present on fruits, can produce mycotoxins (Chapter 53), but because moldy fresh fruits are unlikely to be ingested, mycotoxins are of less importance in fresh fruits than they are in processed products such as fruit juices and dried fruits. The formation of patulin by *Penicillium expansum* in rots occurring in apples is a major problem in the production of apple juice (see Chapter 31), and the formation of aflatoxin is a problem in dried figs (see Section 27.9).

27.6 CONTROL OF MICROBIOLOGICAL SPOILAGE OF FRESH FRUITS

27.6.1 Preharvest Measures

Measures to prevent both field disease and postharvest spoilage start in the field. Cultivars differ greatly in their susceptibility to disease. Plant breeding and "genetic engineering" aim to produce new cultivars that are resistant to disease and have improved postharvest quality. For example, melons with a thick skin and raspberries with a firm texture are less susceptible to damage and therefore to infection.

The state of health of the planting material, whether seeds or cuttings, is an important factor in reducing disease and spoilage. Many fungi and bacteria persist in or on planting material, and can cause disease in the field and after harvest. Examples are the organisms that cause black rot of pineapples and bacterial canker of tomatoes. Plant health regulations exist to limit the movement of disease organisms within and between countries, and seed certification schemes have been established for many crops.

During growth, cultural practices can be used to reduce disease and spoilage.[62] Factors such as density of planting, orientation of rows, shading, mulching, tillage, irrigation, fertilizer regime, weed control, and application of fungicides all influence the health of the crop. Cultural practices such as pruning of fruit trees, destruction of crop debris, and crop rotation are important. Integrated pest management (IPM, in which "pest" encompasses "disease" and "weed") aims to coordinate control measures in the most efficient way.[93] This includes the use of fungicides and of biological control.

27.6.2 Harvesting and Handling Techniques

The choice of harvesting date and its relation to the maturity of the crop is of great significance, especially for fruits stored for extended periods.[35,61] Fruits destined for the fresh market are harvested mainly by hand; human pickers can select for maturity and, with proper training, can keep damage to a minimum. Machines harvest the entire crop at one "pass" and can cause substantial damage even when used correctly. Mechanical harvesting is used mainly for the more "robust" commodities and for crops that are intended for immediate processing. Further handling of the crop during transport and packing has a major effect on damage and infection. The presence of plant debris and cull-piles of rotting produce is a source of infection for the crop during harvesting and in the packhouse after harvesting.

27.6.3 Postharvest Treatments

Many chemicals, including fungicides, bactericides, and plant growth regulators, are applied to fruits after harvest.[123] Regulations for approval of the use of these chemicals are designed so that residues in or on the fruit should be less than the maximum residue levels. These are specified under European Community Directives that are implemented in Pesticides Regulations in the UK,[113] maximum residue levels are specified in the US by the Environmental Protection Agency and in other countries by similar organizations. Imported fruits must comply with the maximum residue levels of pesticides specified in the importing country. Postharvest use of chemicals and the resulting residues have been reviewed by Papadopoulou-Mourkidou.[80] Because of the risk of development of fungicide-resistant strains of fungi, it is recommended that a range of chemically unrelated compounds be used at different stages, for example, before and after harvest and before and after storage for repacking. As examples of use, sodium orthophenylphenate (SOPP) and either thiabendazole or imazalil are used to prevent spoilage of citrus fruit by *Penicillium* spp.; thiabendazole or imazalil are used to prevent postharvest wastage of bananas; and a mixture of carbendazim and metalaxyl is used for the treatment of apples, and iprodione for pears. Thiabendazole is active against a wide range of fungi. Imazalil, prochloraz, and iprodione are effective against alternaria rot. Etaconazole, propiconazole, and guazatine were among the first compounds effective against geotrichum sour rot. Dichloran is effective specifically against rhizopus rot, and metalaxyl and fosetyl aluminium inhibit phytophthora rot. There is an increasing interest in biological control of postharvest diseases.[20,32,55,68,134]

Heat treatment of fruit using hot water at 40° to 60°C for between 30 seconds and 10 minutes, or hot air at 43° to 54°C for 10 to 60 minutes, or hot water containing fungicides may be useful in reducing fungal spoilage of some fruits.[2]

The main antibacterial in the postharvest treatment of fruits is chlorine used in washing water, for example, for tomatoes and peppers. Care is needed to maintain an effective concentration of free, available chlorine, and the effect of the chlorine is mainly to prevent the spread of bacteria in the wash water rather than to kill bacteria on the surface of the fruit. Chlorine dioxide is used also to prevent the spread of bacteria in wash water.

Growth-regulating chemicals are used widely after harvest; ethylene is used to hasten ripening, and auxins and gibberellins to retard ripening. Some fruits, particularly apples, are treated with a calcium drench, which helps to protect against physiological disorders and fungal decay.[23,56] Semi-permeable coatings can reduce respiration rate.[26] Artificial waxes inhibit moisture loss, may also modify respiration, enhance the appearance of some commodities, and may reduce spoilage. Waxes may also be used as a vehicle for a postharvest fungicide, eg, for the application of imazalil to citrus fruits. Fruits such as citrus may be enclosed in individual plastic film bags, which are then heat-shrunk ("seal-packaging"). This, in conjunction with fungicide treatment, can extend storage life.[101] These treatments to optimize the physiological condition of the fruit also minimize its susceptibility to microbial spoilage.

Irradiation has potential uses in the preservation of fruits. In most cases, fruits are more sensitive to irradiation than are microorganisms, an exception is the strawberry. Thus the major aims of irradiation of fruits are to delay ripening and for disinfestation.[131] Combinations of irradiation and other treatments have been investigated for reduction of the microbial load on fruits.

27.6.4 Cooling

Cooling promptly after harvest is important to remove field heat and to lower the temperature of the fruit near to its optimum storage temperature.[120,122] It is recommended that highly perishable temperate fruits such as strawberries and apricots be cooled to as low a temperature as possible, above 0°C, within 6 hours of harvest.[59] The majority of other fruits should be cooled to their optimum storage temperature within 12 hours of harvest, with the exception of melons and certain stone fruits. Hydrocooling by spraying, drenching, or immersion is used for fruits such as apples, peaches, and melons, although cooling with cold air is used more commonly. Hydrocooling by immersion has the disadvantage that cooling water and contaminating microorganisms may be drawn into the fruit through the stem scar, stomates, or damaged tissue as it cools.[3,136]

27.6.5 Storage

Storage at optimum temperature and relative humidity is the most important method of maintaining the quality of fresh fruits and minimizing spoilage during storage.[42,60,74,120] Storage in optimum conditions maintains the quality of fruit by minimizing loss of water, slowing the rate of respiration, minimizing susceptibility to microbiological spoilage, and inhibiting the growth of microorganisms. Some fruits can be stored at temperatures near 0°C, which severely limits the rate of growth of microorganisms, but others, especially tropical and subtropical fruits, suffer physiological damage (chilling injury) if maintained at relatively low temperatures (in some cases as high as 14° to 16°C),[127] making the injured tissue especially prone to fungal invasion, particularly by *Alternaria* and *Cladosporium* spp.

Controlled atmospheres are used for some fruits,[121] notably for apples, pears, and avocados. In some cases, controlled atmospheres containing optimum concentrations of oxygen and carbon dioxide may slow the respiration rate and ripening changes. Removal of ethylene generated by the fruit helps to delay the onset of ripening. Examples of the optimum conditions for storage of selected fruits are shown in Table 27-5.

27.6.6 Packaging

Prepacks of produce for retail sale are sometimes prepared before shipment but more usually are prepared shortly before distribution to retail outlets. Sealed plastic films, with appropriate permeabilities to gases and to moisture, can be used to form packs in which the atmosphere is modified partly by packing under an appropriate gas mixture and partly by the respiration of the fruit.[61,95] The modifed atmosphere is liable to alter during the shelf life of the produce but it retards deterioration of the produce in a similar way to controlled atmosphere. Modified atmosphere packaging is used, for example, to extend the shelf life of apples and tomatoes.

27.7 CONTROL OF MICROBIOLOGICAL SAFETY OF FRESH FRUITS

27.7.1 General Principles

Contamination of fruit with foodborne pathogenic microorganisms can occur at all stages of growth, harvesting, handling, and marketing. Conditions in the field during growth and harvesting are a major critical control point[51] and contamination at this point is difficult to eliminate later by treatment with antimicrobial agents. In a guide to minimizing microbial food safety hazards for fresh fruit and vegetables, the US Food and Drug Administration (FDA)[38] stressed the following principles:

1. Prevention of microbial contamination of fresh produce is favored over reliance on corrective actions once contamination has occurred.
2. To minimize microbial food safety hazards in fresh produce, growers, packers, and shippers should use good agricultural and management practices in those areas over which they have control.
3. Fresh produce can become microbiologically contaminated at any point along the farm-to-table food chain. The major source of microbial contamination with fresh produce is associated with human or animal feces.
4. Whenever water comes in contact with produce, the source and quality of the water dictate the potential for contamination. The potential for microbial contamination from water used with fresh fruits and vegetables should be minimized.
5. Practices using animal manure or municipal biosolid wastes should be managed closely to minimize the potential for microbial contamination of fresh produce.

Table 27-5 Examples of Recommended Conditions for Commercial Holding and Storage of Selected Fruits[a]

Fruit	*Temperature Range (°C)*	*O_2 Concentration (%)*	*CO_2 Concentration (%)*
Apples	0–4	2–3	1–2
Apricots	−1–0	2–3	1–2
Grapes	−1–0.5	2–5	1–3
Peaches	−1–0	1–2	5
Pears	−1–0.5	2–3	0–1

Tomatoes, mature green	12–15	3–5	—
part-ripe/ripe	10–12	3–5	—
ripe	8–10	—	—

[a]Many of these fruits are usually stored in refrigerated air rather than in controlled atmospheres.

Source: Data from Kader[58] and Snowdon.[103,104]

6. Worker hygiene and sanitation practices during production, harvesting, sorting, packing, and transport play a critical role in minimizing the potential for microbial contamination of fresh produce.
7. All applicable local, state, and federal laws and regulations for agricultural practices, or similar laws, regulations, or standards for operators outside the US, should be followed.
8. Accountability at all levels of the agricultural environment (farm, packing facility, distribution center, and transport operation) is important to a successful food safety program. There must be qualified personnel and effective monitoring to ensure that all elements of the program function correctly and to help track produce back through the distribution channels to the producer.

Evidence shows that several of the outbreaks shown in Table 27-4 associated with *E. coli* O157, *Salmonella*, and *Cryptosporidium* have resulted from contact of fruit with animal manure. Untreated, improperly treated, or recontaminated manure or biosolids may contain pathogens that can contaminate produce.[38] Some microorganisms, including vegetative bacteria, can survive for long periods after application to soil.[51] Composting of manure can reduce the number of pathogenic microorganisms present but adequate composting treatment is needed in order to ensure that all the compost reaches a sufficiently high temperature for sufficient time to ensure maximum reduction of pathogenic microorganisms. Several guides to composting treatment have been published in the US.[38] Treatment of sewage reduces the level of microorganisms but the numbers that remain can cause contamination of crops. The use of treated sewage sludge as fertilizer must also be controlled closely to minimize the survival and spread of pathogenic microorganisms. In order to avoid a source of contamination of fruits, such as apples and pears, fruit should not be collected from the ground in orchards used for grazing.

Some of the outbreaks shown in Table 27-4 were attributed to contamination of water applied to crops. Measures are needed to minimize contamination of surface water and ground water with pathogenic microorganisms and to prevent contamination of crops from water supplies in the field during irrigation, harvesting, and processing.[38]

Some outbreaks may have been caused by contamination of crops by workers in the field. Others have resulted from contamination during processing and retail sale. In order to prevent this, detailed guidance for good hygienic practices by workers during growing, packing, holding, and transport of food is available.[38]

Several outbreaks of salmonellosis have been associated with melons (Table 27-4). Because melons are grown on the ground, it may be difficult to prevent contamination with foodborne pathogenic microorganisms. Sampling of melons imported into the US in 1990 and 1991 showed that many serotypes of *Salmonella* were isolated from approximately 1% of rinds.[14] While large companies were reported to wash melons and dip them in chlorine solutions, field-packed melons did not receive such treatment.[118] If melons with a contaminated rind are cut, the edible part may be contaminated by the cutting knife and maintenance of the cut melon at ambient temperature can result in growth of pathogenic bacteria. It is recommended, therefore, that melons be cleaned thoroughly with potable water before cutting, that clean and sanitized utensils and surfaces be used, and that cut melons be kept at a temperature lower than 7°C until served or sold.[14] If not refrigerated, cut melons should be kept for less than 4 hours. In addition, transfer of *S. montevideo* into the inner tissue of tomato by cutting has been demonstrated.[64]

27.7.2 Treatment of Fruits with Antimicrobial Agents to Inactivate Pathogenic Microorganisms

Prevention of contamination is preferred over corrective action once contamination has occurred.[6,38] Antimicrobial chemicals such as chlorine are useful in preventing the accumulation of microorganisms in processing water. These chemicals are less effective in inactivation of microorganisms on produce but, if properly controlled, can reduce numbers. If fruit is treated by immersion in wash water containing an antimicrobial agent, the temperature of the wash water should, ideally, be at least 10 degrees C higher than that of the fruit, in order to minimize uptake of water and of contaminating microorganisms through stem tissue, stomates, or damaged tissue.[6] Washing with water can reduce the number of microorganisms on produce but even with the addition of the usual concentrations of antimicrobials (eg, 100 mg free available chlorine l^{-1} at pH 6.5 for 20 minutes[67]), the reduction may only be of the order of 10- to 100-fold.[6,38]

Chlorine, added as a gas or as hypochlorite, is hydrated in solution to form hypochlorous acid, which has a pK of about 7.5 and dissociates to give the hypochlorite ion. The antibacterial activity of chlorine solutions is due mainly to hypochlorous acid and is influenced strongly, therefore, by the pH of the solution. A pH of 6.5 to 7.0 is suitable; below pH 6.0 hypochlorite solutions are too unstable for use. Because chlorine combines rapidly with organic materials and is then largely inactivated, it must be added repeatedly to maintain the required concentration of free, available chlorine (chlorine present as hypochlorous acid plus hypochlorite). The upper limit on the total concentration of chlorine used will depend on any damaging effect on the plant tissue and on the occupational exposure limit for workers.[6] When tomatoes and apples (to which wax had been applied before purchase) inoculated with *Salmonella*, *E. coli* O157, or *Listeria monocytogenes* were treated by spraying with a solution containing 2,000 ppm chlorine in 0.05 M phosphate buffer pH 6.8, the number of these pathogens was reduced by between 0.35 and 2.30 log cfu cm^{-3} more than by similar treatment with water.[8]

In addition to chlorine, treatments with chlorine dioxide, trisodium phosphate, organic acids, hydrogen peroxide, and ozone have been investigated as a means of decontamination of produce. In the US, chlorine dioxide at a maximum concentration of 200 ppm is allowed for treatment of equipment for processing fruit and vegetables, but a maximum concentration of 5 ppm is allowed in water for washing whole, fresh fruit.[6] Concentrations of up to 5 ppm can be useful for reducing the numbers of microorganisms in wash water but are not effective in reducing numbers on the surface of fruit. Ozone may be useful for preventing a build-up of microorganisms in process water. None of the alternative antimicrobial chemicals appears to be more effective than chlorine for decontamination of fruits. Irradiation might be a means of reducing vegetative bacterial pathogens on raw fruits but only if this treatment proved to be economic and acceptable to consumers[6] and if it is effective in conditions that do not damage the fruit.

27.8 FROZEN FRUITS

27.8.1 Processing and Its Effect on Microorganisms

Some fruits, such as strawberries, raspberries, and cherries, may be frozen whole. These and other fruits are sometimes sliced before freezing or may be frozen as sweetened products blended with sugar.[91] They are also chopped and sieved and frozen as purees. Fruits such as cherries are pitted before freezing and may be blanched in order to inhibit enzymic activity.[70] Slicing and sieving will tend to introduce microorganisms from the processing equipment and the addition of sugar is likely to protect microorganisms from damage during freezing. Freezing and storage at freezing temperatures can damage microorganisms, and freezing in acid conditions is liable to damage food poisoning bacteria more than freezing at neutral pH (see Chapter 6). The outbreaks of infection with *Salmonella typhi* and with viruses transmitted on frozen fruit (Table 27-4) illustrate the ability of these microorganisms to survive the freezing process. Growth of microorganisms is prevented in frozen foods but microorganisms are liable to survive freezing (and thawing), and they may die only slowly during storage of the frozen fruit (see Chapter 6).

27.8.2 Control of Microbiological Safety and Quality of Frozen Fruits

Evidence from the few reported outbreaks of disease associated with frozen fruits and information about the effect of freezing on microorganisms (see Chapter 6) indicate that major factors in controlling the microbiological safety and quality of these products are limitation of the microbiological contamination of the fruit used and the use of good hygienic practices during processing (Section 27.7.1).

27.9 DRIED FRUITS

27.9.1 Processing and Its Effect on Microorganisms

Fruits that are dried commonly include raisins, prunes, dates, apples, figs, apricots, and peaches. Many are sun dried, giving a product with less than 25% water.[109] Dehydrated fruits, which are often used in other products, are produced by a process that reduces the water content to 1% to 5%. Because the water activity (a_w) of most sun-dried fruits is less than 0.65, they do not support the growth of microorganisms. Some types of fruit, including peaches, apricots, pears, and bananas, are treated with 1,000–4,000 mg sulfur dioxide (SO_2) l^{-1} before drying, to inhibit enzymic browning; this treatment also destroys many of the microorganisms that were on the original fruit. Other fruits, including prunes, dates, figs, and vine fruits, are not necessarily treated with sulfur dioxide.[52] Some of the factors that are important in relation to the microbiology of dried fruits are illustrated by consideration of prunes, raisins, and figs.

Prunes

A prune is defined as a dried plum with a moisture content reduced to 19% to 35%,[106] a_w 0.65 to 0.83.[10] The major sources of prunes are the US (California), France, and Chile.[106] Production in California was described by Somogyi.[106] Prune plums are allowed to ripen on the tree. Most of the crop is shaken from the tree by mechanical shakers, caught on canvas frames, transferred to bins, and transported for dehydration (this has replaced sun drying). Before drying, the fruits are cleaned with air blast and water sprays and dipped in water. They are then spread on trays and dried, usually under forced-air flow for about 24 to 36 hours, to about 18% moisture, then sorted and packed. For prunes with a moisture content higher than 25% or a water activity above 0.7 either pasteurization or the addition of potassium sorbate, as a dip or spray, is recommended. In order to improve ease of handling for some purposes, coatings are applied. These coatings may be vegetable oils, mono- and di-glycerides, dextrose, starch, rice powder, or, for prunes with <4% moisture, calcium stearate. In order to supply a ready-to-eat product, dried fruits may be rehydrated to a water activity of 0.85 to 0.90 before packing; they are treated with hot or boiling water, which destroys many of the contaminating microorganisms. Up to 0.1% potassium sorbate or sodium benzoate is added to these high-moisture dried prunes to prevent growth of yeasts and molds.

Raisins

Drying of grapes to produce raisins is described by Striegler, Berg, and Morris.[115] The major producing countries between 1979 and 1993 were Turkey and the US.[37,115] For the production of raisins in California, grapes may be sun dried on trays in the field for more than 7 days and then cleaned on a screen shaker to remove foreign and substandard material. Depending on weather conditions during sun drying, mold growth tends to occur on the grapes. Reconditioning is used to improve the quality of such raisins. This process involves passage over screen shakers, washing in hot water (70°–80°C), and further drying on trays at about 60°C for 20 to 25 hours.

Raisins are also produced by dehydration in bulk bins. They are first dipped in hot water (80°C + 0.25% NaOH or 99°C), washed in fresh water, and spread on drying trays. Golden seedless raisin grapes are then exposed to SO_2 gas at 2,000 to 4,000 mg l^{-1} for 4 to 6 hours, whereas dipped seedless raisin grapes are not treated with SO_2. Both types are then dried in a counterflow of hot air at temperatures in the range 57° to 74°C for about 24 to 36 hours.

In the past, unprocessed raisins were stored commercially in stacks and fumigated periodically with chemicals such as methyl bromide or phosphine to eliminate insect infestation. Because of environmental concerns, alternative methods are now being used, in particular storage in stacks that are purged of oxygen and in which a low-oxygen atmosphere is maintained long enough to kill any insect pests.

During processing, raisins are treated further to remove extraneous material, to break up clusters into individual raisins, and to grade into sizes. They are then spray washed with cold water, passed through wash tanks, passed over a dewatering shaker and through further cleaners, inspected, and sorted. A coating of food-grade oil or other material may be applied depending on the requirement of the end user. In the US, the final product is inspected by US Department of Agriculture (USDA) inspectors and must have a moisture content of <18%.

Figs

Figs have an unusual development and structure. The small flowers are enclosed in a hollow fleshy structure derived from stalk tissue, which has a small opening, the ostiole.[29,31,103] Pollination of most cultivars is by a tiny wasp, which passes through the ostiole. Other insects and fungi can also enter through the ostiole and develop in the interior of the cavity. Some fig cultivars are self-fertile, but these also have an open ostiole through which insects and fungi can enter the cavity. *Fusarium moniliforme,* which causes soft rot of figs, is transmitted into the fig by the fig wasp, and yeasts and bacteria are carried into the fig by fruit flies.

Figs are usually sun dried, often on the ground after falling, and growth of fungi may occur during the drying process. Growth of *Aspergillus* spp. may occur giving rise to formation of aflatoxin in figs.

Glacé Fruits

Glacé fruits are produced by infusing blanched fruit with increasingly concentrated glucose syrups that contain SO_2 as a preservative.[52] The product is then dehydrated at low temperature to reduce the a_w to about 0.85. This processing destroys the majority of the initial microflora.

27.9.2 Control of Microbiological Spoilage and Safety of Dried Fruits

As with other fruit products, practices that limit microbiological contamination in the field, rapid drying, and reduction of contamination on equipment used in transport and processing can help to lower the microbial load on the product. Treatment with sulfur dioxide destroys many of the microorganisms on the surface of fruits. Dried fruits with an a_w lower than 0.65 are not susceptible to microbial spoilage. Unsulfured dried fruits with an a_w higher than 0.65 are liable to spoilage, particularly by *Eurotium* species (see Chapter 7), and potassium sorbate may be added as a preservative. High-moisture prunes are susceptible to spoilage by *Eurotium* species and *Xeromyces bisporus* unless they are treated with an antifungal compound or heated in a hermetically sealed container (see Chapter 7). Potassium sorbate is added commonly to high-moisture dried fruits. Growth of yeasts and molds on high-moisture prunes was limited by the addition of up to 0.1% potassium sorbate or sodium benzoate.[98]

Several surveys have shown unacceptable levels of aflatoxin in dried figs.[52] In the United Kingdom (UK) (and also in the European Community) the statutory limits for aflatoxin in dried figs are as follows:[73]

- 4 μg kg^{-1} total aflatoxin for dried figs and their products for sale or for incorporation in any compound food or for import for direct human consumption
- 10 μg kg^{-1} for such imports intended for further processing before sale or incorporation in any compound foods for human consumption.

Surveys between 1988 and 1992 of whole dried figs imported into the UK, mainly from Turkey, showed that during this period the percentage of figs containing >4 μg aflatoxin kg^{-1} decreased from 26% to 16%; however, some samples contained >50 μg kg^{-1}.[73] Consignments of whole dried figs and fig paste that contained >10 μg aflatoxin kg^{-1} were refused entry into the UK by port authorities. During the period of this survey, screening of figs under UV light was introduced, based on the correlation between blue/green/yellow fluorescence on the outside of figs and high aflatoxin level.[100] This technique offers a method for improved testing of samples.

Although SO_2 is used in the production of glacé fruits, it is only partially effective as an antimicrobial because free SO_2 is bound rapidly by glucose.[52] Spoilage of partially prepared glace pineapple by *Schizosaccharomyces pombe* has been described and associated with the resistance of this yeast to SO_2 combined with its ability to grow at reduced a_w.[52]

27.10 CANNED FRUITS

27.10.1 Processing and Its Effect on Microorganisms

In foods with a pH of 4.6 or lower, growth of *Clostridium botulinum* is inhibited (see Chapter 41). The thermal processes for acid canned foods, ie, foods with a pH of 4.6 or lower (US) or with a pH of 4.5 or lower (UK), are much less than an F_0 3 process required for low-acid foods (see Chapters 3 and 41) and are based on the need to inactivate vegetative microorganisms and spores that are able to result in growth in the final product. In the case of canned fruits, these treatments normally involve heating at <100°C. Following washing, peeling (with the use of alkali in peeling some fruits[89]), and grading, many fruits are blanched by heating briefly at 88° to 99°C to inactivate certain enzymes that would cause deterioration of flavor and texture. The fruits may then be exposed to sulfur dioxide either by dipping in a solution containing 2,000 to 4,000 mg SO_2 l^{-1} for 2 to 5 minutes or by fumigation. Acidulants and antioxidants such as ascorbic acid are often added, and sugar may be included. If heat treatment during canning is insufficient, canned fruits are liable to spoilage by surviving microorganisms.

Canned Fruits with a pH in the Range 3.7 to 4.6

These products include canned fruits such as tomatoes, pears, and figs. There are reports of spoilage by spore-forming bacteria including the butyric acid clostridia, *Clostridium pasteurianum* and *C. butyricum*, and also by *Bacillus coagulans*. Spores of *B. coagulans* are reported to be more heat resistant than those of *C. pasteurianum* and *C. butyricum* but spoilage by the *Bacillus* appears to require a higher pH than spoilage by the *Clostridium* spp.

Clostridium pasteurianum or similar bacteria that were reported as the cause of canned fruit spoilage could initiate growth from vegetative bacteria in pear and apricot juices with a pH of 3.6.[54,123] Bacteria similar to *C. pasteurianum* were reported as the cause of spoilage and swelling of batches of canned pineapple with a pH of 4.4.[107,108] *C. pasteurianum* and *C. butyricum* have been reported to cause spoilage of canned tomatoes.[46] Organisms similar to *C. pasteurianum* were reported to multiply and cause spoilage in canned mandarin orange at pH 3.90 to 3.97 and higher, and consequently it was recommended that the product should be adjusted to a pH below 3.5.[50] Commercially canned pears were reported to have a pH in the range 4.1–4.3 and a water activity (a_w) of about 0.985;[54] two strains (both *C. pasteurianum*) of seven strains of butyric anaerobes tested multiplied in pear juice in these conditions. Adjustment of the water activity of pear juice with sugars was suggested as a means of preventing growth of *C. pasteurianum*, and it was concluded that for an a_w range of 0.97 to 0.98 the pH of the product should be less than 4.0. It was suggested that appropriate combinations of pH and a_w might reduce the heat processing needed for canned pears.

Some acid and acidified canned fruits, in particular tomato products, are susceptible to spoilage by *Bacillus coagulans* resulting in "flat-sour" spoilage, so called because the bacteria produce acid but no gas from carbohydrates, cause off-flavors, and do not cause swelling of cans. In the mid-1950s, it was realized that the pH of some tomatoes was in the range 4.5–4.8.[87] At pH higher than 4.3, the risk of spoilage of canned tomatoes increases, and in the range pH 4.5–4.8, the risk of botulism appears. Therefore, in canning high-pH tomatoes, organic acids should be added to lower the pH.[21,87] The vegetative cells of some strains of *B. coagulans* can multiply in culture media at pH 4.05 and in tomato juice at pH 4.15 to 4.25, but heated spores failed to germinate and give growth in tomato juice adjusted to a pH lower than 4.3.[36,82] *Bacillus coagulans* is described as a thermophilic or facultatively mesophilic bacterium[116] and the temperature range for its growth was reported as 28° to 65°C,[36] but growth at temperatures as low as 18°C has been reported.[99] This bacterium originates from soil, it can become established in tomato processing plants, and large numbers may accumulate in water used for washing tomatoes. Because sugar and starch may be sources of the bacterium, products used in canned fruit should be subject to standards for these bacteria.

The recommended sterilization value of a process for whole canned tomatoes in juice against spores of butyric acid anaerobes when the pH is above 4.3 was the equivalent of 10 minutes at 200°F (about 93°C) and assuming a z-value of 15 degrees F (8.3 degrees C) (see Chapter 3 for a definition of z value), and when the pH is less than 4.3, the equivalent of 5 minutes at 200°C.[76,135] Against spores of *B. coagulans* at pH 4.5, the recommended process was the equivalent of 0.7 minutes at 250°F (121°C) assuming a z-value of 18 degrees F (10 degrees C). York et al.[135] concluded that a marginal heat treatment of tomato products containing spores of *B. coagulans* so damaged the spores that they were unable to germinate and give growth in the tomato product at pH ≤4.3. They reported that at pH ≤4.3 after a heat treatment (calculated on the basis of the heating throughout the product) equivalent to heating at 212°F (100°C) for 1.56 minutes, assuming a z-value of 27 degrees F (15 degrees C), no organoleptic, or microbiological spoilage by lactic acid bacteria, butyric anaerobes, or flat sour bacteria was experienced either commercially or in the laboratory.

Outbreaks of gaseous spoilage of commercially canned fruits by bacteria of the *B. macerans/B. polymyxa* group have been reported.[126] The heat resistance of spores of these bacteria was reported to be comparable with that of the butyric anaerobes. In phosphate buffer pH 7.0, heating at 100°C for about 30 minutes was required to inactivate 10^5 spores of a strain of *B. macerans,* whereas in canned fruit syrup, pH 3.6, heating at 100°C for 1 minute was required. The spoilage was attributed to post-pasteurization contamination of cans by entry of cooling water; the bacteria were present in cooling water and the spores would be sufficiently heat resistant to withstand the temperatures in rotary coolers.[126]

Canned Fruits with a pH Lower than 3.7 to 4.0 (High Acid)

These products are subject to spoilage mainly by molds and to a lesser extent by yeasts and lactic acid bacteria. The ascospores of certain molds, in particular ascospores of *Byssochlamys, Neosartorya, Talaromyces,* and *Eupenicillium* species,[84,109] have the potential to survive the heat treatments used commercially in canning acidic fruits. The main organisms causing spoilage of acidic canned fruits appear to be *Byssochlamys fulva* and *B. nivea.* The following *D* values have been reported for ascospores: *B. fulva* and *B. nivea* in grape juice at 86° to 87.8°C, between 4.8 and 11.3 minutes[7]; *Talaromyces flavus* in apple juice at 92°C, 2.2 minutes; *Neosartorya fischeri* in apple juice at 85°C, 18 minutes; *Eurotium herbariorum* in grape juice at 70°C, 2.5 minutes.[109] *Byssochlamys* spp. are obligate aerobes, but they can grow in very low concentrations of oxygen.[84] Even limited growth may be sufficient to allow the production of pectin-degrading enzymes that cause softening and ultimately complete breakdown of the fruit. Mycotoxin formation by molds of all these genera growing in fruit products has been reported. Some strains of *Byssochlamys* are reported to form byssochlamic acid, patulin, byssotoxin, and malformins[7,109]; production of very low levels of patulin by *Byssochlamys* species in canned fruits has been reported. Fields and orchards are the source of the fungus, which probably survives in plant debris. In New York, *B. fulva* was the predominant mold on sound and decayed grapes, grape vegetation, apples, blackberries, cherries, peaches, raspberries, apricots, pears, and orchard and vineyard soils.[7]

Spore-forming bacteria with a pH optimum at pH 3.4 to 4.0 have been isolated from spoiled fruit juice beverages[111] and subsequently identified as *Alicyclobacillus.*[86,112] Spores of one strain heated in apple juice, pH 3.5, had a D value at 95°C of 2.8 ± 0.7 minutes and a z-value of 7.7 degrees C. Spores of a second strain heated in grape juice, pH 3.3, had a D value at 95°C of 2.4 ± 0.7 minutes and a z-value of 7.2 degrees C, indicating that they could survive the thermal process given to many fruit juices and other fruit products. This organism is thermophilic growing at temperatures from 12° to over 53°C.[86] Spoilage of fruit juices by this bacterium has been reported rarely; it has been isolated from canned diced tomatoes[128] and its significance in relation to canned fruits remains to be determined.

There is a risk that microbial spoilage of some canned fruits may cause a rise in pH of the product and allow growth and toxin production by *Clostridium botulinum*. Between 1899 and 1975, 35 cases of botulism in the US were attributed to "acid foods," of which 34 were home processed and one was commercially processed.[79] In several of these incidents other microorganisms, in addition to *C. botulinum*, were isolated from the toxic product. There is evidence that, in certain conditions, prior growth of a yeast or mold or of *Bacillus licheniformis*, which has survived the heat treatment or has contaminated the product after heating, can raise the pH of the food allowing growth of *C. botulinum*.[75,79]

27.10.2 Control of Microbiological Spoilage and Safety of Canned Fruits

Soil is a source of spore-forming bacteria and there are several examples of situations in which spoilage of canned fruit has been associated with an unusually high level of soiling of the fresh fruit. Heat processes for canned fruit were designed to inactivate spoilage microorganisms at the concentration expected in these foods in conditions of good hygienic practice. The risk that heat-resistant microorganisms will survive heat processing can be reduced by using good quality fruit that shows no signs of latent infection, by minimizing contamination of the fruit with soil, by thorough washing, and by preventing build-up of microorganisms in wash water and on processing equipment. Because of the importance of minor ingredients as a source of contamination, particularly with spores of *Clostridium* and *Bacillus* spp., it is recommended that ingredients such as sugar, starch, and spices, used in canning should comply with standards limiting the number of spores of these bacteria present (see Chapter 35). Control of the pH for all canned foods is essential, and at the higher limit of the pH range, control of water activity may also be important. Prevention of leakage of cans during cooling and minimizing contamination of cooling water are also important (see Chapter 3).

27.11 CONCLUDING REMARKS

Throughout this chapter it is clear that conditions during growth of fruits influence contamination and affect the microbiological safety and quality of both fresh and processed products. Changes taking place in agricultural practices, including the greater use of animal waste and municipal waste on land; the increasing use of fruits grown in, and transported from, all parts of the world; the use of new techniques for processing including new methods of thermal treatment; and the development of novel types of product may give rise to new problems.

A significant proportion of fruit is liable to be wasted by spoilage after harvest. Much of this spoilage could be prevented by good agricultural practices that minimize the inoculum level of spoilage microorganisms, by the use of optimal storage conditions, and by careful handling so as to minimize physical damage to the produce. There is a continuing need to ensure that people handling fruit during harvesting, packing, transport, and retail sale do so in a way that minimizes damage to the product. Extreme care in the field and throughout postharvest handling can be wasted by careless handling during transport, display, and retailing.

28.1 INTRODUCTION—THE IMPORTANCE OF CEREALS

Cereals, the fruits of cultivated grasses of the monocotyledonous family Gramineae, are arguably the most important agricultural crops in the world. The eight principal cereal crops are wheat, rice, maize, barley, sorghum, millet, oats, and rye. Kent and Evers[73] explained the technology of cereals in some detail, including summary statistics for production and use.

The total world production of cereals has increased dramatically during recent history. In 1960, the total world cereal crop was over 900 million metric tons, whereas by 1987 to 1989 the annual crop had risen to 1,784 million tons. Wheat, rice, and maize were the dominant crops throughout this period and the majority of the total increase in production was due to larger crops of these three cereals. In 1960, their combined total was approximately 700 million tons, rising to about 1,500 million metric tons in 1989. Each provided a similar contribution to the total world harvest throughout this period but wheat has been slightly ahead of the other two since the early 1970s (Figure 28-1). The total world barley crop also doubled over the same period but was only 170 million metric tons in 1989. Production of the other four cereals—sorghum, millet, oats, and rye—hardly changed over the period. The increase in production has been associated with only a small increase in the total land area given over to cereals and is mainly due to higher yields.

Wheat is grown worldwide but is most successful in temperate to subtropical climates with moderate annual rainfall (229–762 mm) and a mean summer temperature of 13°C or more. Where winters are not too severe, seed can be sown in autumn. In countries with severe winters, wheat is sown as early as possible in the spring to be harvested before the first autumn frost. Two-thirds of the world wheat crop is used for human consumption and about a fifth for feedstuffs. About 7% is used for seed with the remaining small amount being used in industrial processing, such as starch production, gluten extraction, pharmaceuticals manufacture, and some waste.

Rice is grown in the tropics and some temperate regions. Although normally grown in water-covered fields, it can be grown on dry land. There are varieties that are adapted to a wide range of environmental conditions. Nearly all the world rice crop is used for human consumption.

Maize can be grown in tropical or temperate regions which have at least 90-day periods without frosts and gives its highest yields when it can mature in 130 to 140 days. A little under two-thirds of world maize production is used for animal feeds and only one-fifth for human consumption, although it is a

staple in some countries in Latin America and in parts of Africa. The remainder goes for industrial processing into starch, sugars and syrups, industrial spirits and whiskey, and about 1.5% for seed.

Barley is a temperate crop with a distribution and requirements similar to those of wheat. Its principal uses are in animal feeds, malting, brewing, and distilling.

Sorghum is grown in tropical regions (latitudes below 45°) and is favored by a mean temperature of 27°C. It forms the staple food in many parts of Africa, Asia, and Central America with one-third of the world crop being used for human consumption. Over half the total crop is used for animal feed and the remainder is used in industrial processing and as seed.

Millet is the name given to at least 12 species of small-seeded grasses. Often grown under adverse conditions of heat, limited rainfall, and unfertile soil, it is a relatively low-yielding crop but does better than other cereals in these conditions. Most millet is used in the country of production and three-quarters goes for human food. About 3% is saved for seed and the remainder is split equally between animal feed and industrial processing.

Oats are a temperate crop, more successful in wet climates than wheat or barley but less tolerant of cold. The majority of the oat crop is used in animal feeds. A variety of human food products are made from oats but these use only 5% of the world crop.

Rye is more resistant to pests, diseases, and cold than wheat and performs better on poor soils. Therefore, it tends to be grown on land just outside the belt giving the best wheat crops. Rye is the main bread grain of Scandinavian and eastern European countries, but worldwide only a third of the rye crop is used for human consumption.

28.2 MICROFLORA ON CEREALS IN THE FIELD

Cereals in the field are exposed to microorganisms from the soil, birds, animals, insects, manures, and from other plants in the field, particularly if diseased. A number of important fungal diseases of cereals may also be carried on the seeds themselves.[26] Thus, there is ample opportunity for microbes to contaminate the developing grains.

The most important factor governing the subsequent colonization of the grains, whether by saprophytes or pathogens, is the availability of water.[88] Hence, weather is important in determining the rate of microbial colonization of grain. Seiler[164] showed this quite clearly for wheat grown in the United Kingdom (UK) in 1976, a hot dry summer, and in 1977, an unusually wet one (Figure 28-2).

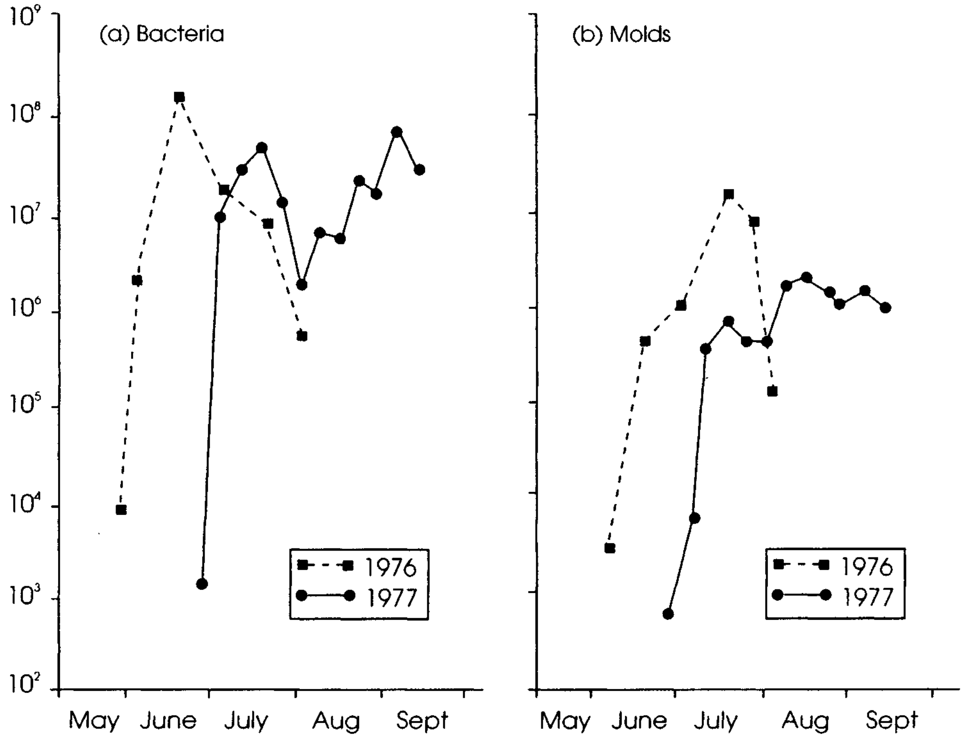

Figure 28-2 Numbers of Bacteria and Fungi on UK Wheat in the Field during Two Growing Years. The summer was long, hot, and dry in 1976, whereas the summer in 1977 was wet.

Peak numbers of both bacteria (*ca.* 10^8 g^{-1}) and molds and yeasts (10^6 to $10^7 g^{-1}$) were similar in both years. However, the populations peaked earlier in 1976 with a sharp decline over four dry weeks preceding the early harvest, whereas in 1977 the populations peaked shortly before the harvest.

Trojanowska collected cereal grains within a month of harvest in Poland for four years and the largest population of fungi occurred in 1980 when July and August were wet, with high average humidity and low sunshine.[189] The lowest population occurred in 1983 when average humidity was low and sunshine high, although there was some rain at the beginning of August. Populations on wheat, barley, and rye all followed similar patterns in relation to the weather. The relationship between weather and microbial population, however, is unlikely to be a simple one.

Microbes begin to colonize ripening grain soon after the ears emerge. Bacterial numbers rise first, closely followed by yeasts, yeast-like fungi, and filamentous fungi.[88] A bacterial population in excess of 10^8 g^{-1} has been observed on growing wheat.[164] Bacterial populations of 10^5 to 10^7 g^{-1} have been observed in wheat at harvest,[164] and on rice.

The yeasts most commonly isolated in temperate regions include *Cryptococcus laurentii*, *C. albidus*, *Rhodotorula (Torulopsis) ingeniosa*, *Sporobolomyces roseus*, and *Rhodotorula glutinis*.[88]

Many different filamentous fungi have been isolated from growing and newly harvested cereals in temperate regions including species of *Cladosporium*, *Alternaria*, *Verticillium*, *Eppicoccum*, *Fusarium* (including *F. culmorum*, *F. graminearum*, and *F. avenaceum*), *Botrytis*, *Dreschlera*, and *Monilia*.[88,189] Together these and other fungi that prosper in the high-moisture grain in the field are known as "field fungi." The colonization of cereals by individual fungi is highly variable (Table 28-1). *Alternaria alternata* has been detected in up to 100% of wheat kernels at the point of harvest.[28] *Cladosporium* spp. have been detected in over 90% of barley grains, even after a period of storage.[47] Colonization by *Fusarium* spp. is increased by rain and by "lodging," when the crop is knocked down by rain and wind and remains damp for a long period.

In warmer climates the predominant species are similar, but other fungi have also been found, including species of *Curvularia*, *Cochliobolus*, *Phoma*,

Penicillium, and *Aspergillus.* The last two genera would be considered primarily as storage fungi in temperate areas but appear able to colonize grains in the field when provided with higher temperatures and humidities. There may also be a change in the dominant species of each genus, eg, the dominant *Fusarium* species is more likely to be *F. semitectum* or *F. moniliforme,* particularly on maize.[88]

The presence of the majority of microorganisms appears to be of no consequence to the grain. A number of pathogenic fungi, however, can cause serious quality losses before harvest[12,26,59,76] or loss of crop yield and hence loss of value in trade.

More significantly, many species of fungi are known to be capable of producing mycotoxins on cereal grains in the field or in storage (see Chapter 53).[82,108] The first human disease to be associated with consumption of grains infected with a fungus was ergotism. Primarily associated with rye, the ergot fungus *Claviceps purpurea* can infect all the principal cultivated cereals to some degree.[100] From the middle ages to the late 19th century there were many epidemics of "St. Anthony's Fire" throughout Europe[18] particularly when a warm spring was followed by a wet summer. Improvements in farming and milling practices mean that ergotism is now considered a disease from the distant past. However, it is sobering to realize that a well-described epidemic occurred in the village of Pont-Saint-Esprit in southern France as recently as 1951[46] and outbreaks in developing countries were reported in the 1970s.[15]

In recent years attention has focused on other mycotoxins. In cereals in the field, aflatoxin produced by *Aspergillus flavus* or *A. parasiticus* has been found in maize[3,57] and sorghum[3] grown in tropical regions. Zearalenone produced by *Fusarium* species has been found in maize from the United States (US)[3] when conditions favored *Fusarium* ear rot and in wheat, barley, oats, and maize grown in New Zealand,[86] albeit at low levels. Fumonisins produced by *Fusarium* species have been found in maize in several European countries.[198] Deoxynivalenol (vomitoxin) has been identified in Canadian winter wheat[158,186] and in wheat from Kansas and Nebraska following harvest in years when the weather was warm and wet in May and June.[16,101] Hence, whenever conditions allow growing cereal crops to become infected with mycotoxigenic fungi, the risk of toxins being formed is present.

In practice, the presence of mycotoxins in cereals in trade is highly variable. In UK surveys during 1980–1982, 81% of samples of UK grown cereals (barley, wheat, and oats, total 345 samples) did not contain detectable levels of deoxynivalenol and only 4% contained more than 100 μg kg^{-1}. Over the same period, deoxynivalenol was not detected in only 16% of samples of cereals imported into the UK (maize and wheat) and 46% of samples contained over 100 μg kg^{-1}.[4] In surveys of the wheat harvested in the former USSR in 1986–1988, over 80% of samples examined contained detectable deoxynivalenol.[193] In a survey of the American wheat harvest of 1993, about 40% of samples contained deoxynivalenol at levels above the US Food and Drug Administration advisory levels for milling wheat.[191] Similar variability is found in relation to other mycotoxins including ochratoxin[110,195] and aflatoxin[195] with other cereals. Methods for detecting mycotoxins are now extremely sensitive and regulatory authorities have tended to be cautious, recommending limits for mycotoxins in foodstuffs, which creep down in line with analytical advances. It is difficult, therefore, to assess the level of concern that should be given to these results.

The association between weather and microbial activity in cereals, while undoubtedly complex, has led to attempts to identify factors that could be used to predict crop quality and/or disease outbreaks. Weather is known to affect grain quality and rain-damaged grain can have from 4 to 17 times as much α-amylase as undamaged grain.[39] A strong correlation has been shown between α-amylase content of wheat and counts of both bacteria and molds,[95] supporting the belief that wet weather contributes to poor microbiological condition of grain.

Legan and Curtis[95] and Neskorozhenyi and Zelenskaya[118] suggested, independently, that there is a statistical correlation between patterns of solar activity marked by the sunspot cycle and microbiological condition of cereals. Changes in solar activity are known to affect global climate; for example, sea surface temperatures vary with sunspot numbers over a double sunspot cycle.[119] It seems reasonable to assume that local weather conditions may, in turn, be affected, leading to variations in grain quality and microbiological condition. The solar cycle has a duration of approximately 11 years, so to confirm or refute these hypotheses over a number of cycles would involve work on a very long timescale.

28.3 HARVEST, DRYING, TRANSPORT, AND STORAGE

Regardless of the original source of the grain, the pattern of handling has certain similarities. The crop is cut, either mechanically or by hand. The harvest is threshed and winnowed to separate the grains from the chaff either within the mechanical harvester or using labor and the wind. The grains are dried in mechanical dryers using a forced flow of heated air, or using the sun and wind, unless the grain moisture content is low enough to ensure stability in storage. Finally, the grains are stored until sold or consumed; the storage facilities may be to a very high standard of hygienic design and insect proofing, or be no more sophisticated than storage on a barn floor. The storage period may bridge the seasons to the next harvest or be for up to several years in strategic reserves or European intervention "stockpiles." Transport is involved at several stages and may be local, from the field to the farm, or international, even intercontinental.

The fungal flora of the grains changes during postharvest drying and storage. The field fungi are adapted to growth at relatively high water activity (a_w), hence, high moisture content, and they die during drying and storage, to be replaced by a range of storage fungi that are capable of growth at lower a_w.

In 1,299 stored US export maize samples and 1,362 export wheat samples obtained in 1977 and 1978, the most frequently observed storage fungi were from the *Aspergillus glaucus* group. Essentially all maize samples yielded *A. glaucus*, typically in 15% to 30% of kernels, and 80% of wheat samples had detectable *A. glaucus*, typically in 1.5% to 4.0% of kernels.[155] *Penicillium* spp. were found in 7% of maize kernels and 0.1% of wheat kernels. *A. flavus* was frequently found in maize samples but typically only in a small percentage of kernels; whether this was due to preharvest or postharvest invasion was not clear. Other species of *Aspergillus* such as *A. candidus*, *A. restrictus*, *A. versicolor*, *A. ochraceus*, and *A. niger* were found in slightly less than 1% of maize kernels and about 0.1% of wheat kernels. *Cryptococcus albidus* was the yeast found most commonly in wheat samples from six regions of the US. Other yeast species found in wheat were *Cryptococcus laurentii*, *Rhodotorula glutinis*, *Pichia fermentans*, and *Pichia burtonii*.[83] However, only 26 of the 55 wheat samples examined yielded any yeasts.

Storage fungi of rice are primarily *Aspergillus* and *Penicillium* species but *Mucor*, *Fusarium*, *Cladosporium*, *Alternaria*, *Oidium*, and a *Sporendenema* species have also been detected.[31] *Penicillium* species were less prevalent on US rice than on Japanese rice, although no reason for this was apparent. Storage fungi on barley include *Absidia* spp., *Aspergillus glaucus* (group), and *Penicillium* spp.[47]

Fungi isolated in individual studies vary, particularly in the proportions of different fungal species in the population. However, the overall picture is of a storage mycoflora that is broadly similar at a genus level in different cereals from widely separated growing areas.[87,90,179]

Stored cereal grains also carry a bacterial population. The bacteria would be unable to grow in correctly stored grain because of the low moisture content (*ca.* 12% to 15%) giving a water activity of 0.7 or below, so it must be presumed that they represent the remnants of the population growing on the grains in the field plus any contaminants from soil and other causes encountered during growth, harvest, and storage of the grains. Counts of mesophilic aerobic bacteria in wheat range from *ca.* 10^4 to *ca.* 10^6 g^{-1}.[41,60,169] *Flavobacterium* spp. and *Pseudomonas* spp. were isolated from 91% and 82%, respectively, of US wheat samples tested.[60] *Brevibacterium*, *Bacillus cereus*, *Enterobacter cloacae*, and *Bacillus licheniformis* were isolated from less than 30% of samples tested. The numbers of each species present were not determined but the mesophilic aerobic bacterial counts were in the range 3.6×10^4 to -6.6×10^5.

28.3.1 Storage Conditions

Grain in storage must be protected from insects, which are responsible for a high proportion of grain damage,[143] and from fungal spoilage. Damaged grains are more readily colonized by storage fungi.[155] Once colonization has occurred, fungal growth is promoted by high water activity, and hence varies with grain moisture content. It has long been known that grain must be stored at low moisture content if it is to be stable for any length of time. For most grains, moisture contents in the range 10% to 14% are recommended,[40] the exact value depending on the grain type and desired storage life. In practice, the "safe" moisture content of the grain corresponds to that giving an equilibrium relative humidity (ERH) around the grain of 70% (or lower), equivalent to an a_w of 0.70.[19] For a fixed grain moisture content, the ERH rises by about 3% when the temperature increases by 10°C. This has serious implications for grains transported from temperate to tropical climates, which can experience a 20°C or more increase in temperature leading to an increase of 6% ERH (0.06 a_w), significantly increasing susceptibility to mold. Hence, for grain in international transport the loading temperature and likely temperature changes during transit must be considered as well as the moisture content.[109] The relationship between temperature, moisture content, and spoilage of maize (0.5% dry matter loss) is shown in Figure 28-3.

Initial moisture content of grain is not the only factor controlling stability, for water may migrate through the grain under the influence of temperature gradients. Water evaporates from grain in warm areas of the store and condenses in cold sections. Eventually, the local moisture content in the cool section may increase to a value permitting fungal growth. This may be a particular problem when the outside temperature is low relative to the grain temperature, because the natural insulating properties of the grain will retain heat within the center of a bulk store for extended periods. Cold air generated by con-

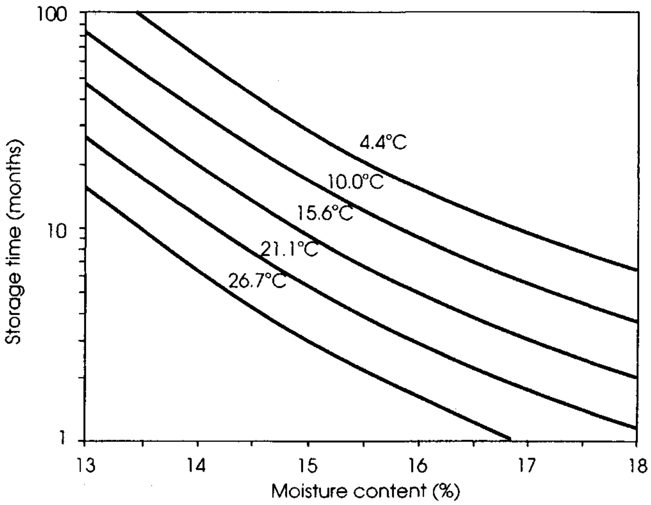

Figure 28-3 Allowable Storage Time for Maize before Spoilage (0.5% Dry Matter Loss) and Probable Loss of Grade Occurs. *Source:* Data from D.B. Sauer, Mold Invasion in Relation to Grain Damage, *Cereal Foods World*, Vol. 33, pp. 489–490, © 1988.

tact with cold bin walls passes down near the walls, into the center of the grain near the bottom, then rises, carrying moisture toward the top. The moisture is then deposited in the cooler surface layers of grain. Hence, ventilation of bulk stored grain is important. Elliot[40] describes the cycle of fungal growth, producing moisture and heat, prompting more fungal growth which can, in extreme cases, lead to spontaneous combustion of badly stored grain.

Molds growing on stored cereals produce a range of volatile odor compounds. Those identified that form a significant proportion of total odor volatiles include 3-octanone, 1-octen-3-ol,[192,206] 2-methylfuran, 2-methyl-1-propanol,[17] styrene,[206] and 3-methyl-1-butanol.[17,192,206] Sampling from the grain store ventilation system for fungal odor volatiles will provide a useful early warning of spoilage problems once the technology is robust enough to be used in such environments.

Storage of Wet Grains

Drying is expensive and can cause quality loss in the grains if not well controlled. Hence, it is no surprise that considerable effort has been invested into techniques for storing wet grain. These techniques fall into three main groups: temperature control, atmosphere control, and addition of chemical mold inhibitors.

Temperature Control. Cooling of wet cereals using refrigerated air has been used to prevent or delay fungal growth but even at temperatures close to 0°C, *Penicillium* spp. can cause spoilage of the grains if their moisture content is high enough. *Penicillium viridicatum* inoculated onto wheat was able to grow during storage at 18% to 20% moisture content and 6° to 12°C, even though other fungal species remained constant or declined in numbers.[115]

The total microbial load in wheat[172] and flour[199,200] can be reduced by storage at elevated temperatures provided that both temperature and holding time are carefully controlled to minimize damage to the wheat proteins. A 90% reduction in bacterial numbers in flour was achieved in 12 weeks at 28°C or 3 weeks at 37°C and a 99.9% reduction in less than 1 week at 48°C.[199,200] In wheat, bacterial numbers were reduced by 90% in 1 to 2 weeks at 44°C, 1 day at 50°C, and about 4 hours at 60°C.[172] It seems that the increased rate of reduction in bacterial numbers results directly from heat damage to the bacterial cells. This process has never found favor in commercial practice, being considered too expensive.

Atmosphere Control. Cereal grains may be stored in modified or controlled atmospheres to control stored-product insects. Typical atmospheres are 1% O_2 in nitrogen and 60% CO_2 in air. Both may be equally effective at controlling insects, but the high CO_2 atmosphere could be more effective at controlling fungal growth. A CO_2 concentration in excess of 15% is required to halve the linear growth rate of a number of field and storage fungi at 0.98 to 0.90 a_w and 23°C, with *Penicillium brevicompactum, Aspergillus fumigatus, A. nidulans,* and *A. versicolor* most sensitive to raised CO_2 of those fungi tested.[66] Mycotoxin production is more sensitive than fungal growth to raised CO_2 and to reduced O_2. However, fungal deterioration cannot be prevented completely in high-moisture cereals (a_w 0.80–0.90) as some fungi, particularly some *Fusarium, Mucor,* and *Aspergillus* species can grow in CO_2 concentrations of 60% to 80%. Yeasts and yeast-like fungi can also develop in high-moisture cereals in controlled atmospheres, causing rancidity and off-odors.[66]

Chemical Mold Inhibitors. Propionic acid is an effective agent for controlling growth of fungi in high-moisture grain and is recorded as preventing mycotoxin production by molds growing on high-moisture maize. Grains treated with propionic acid have the same, or slightly higher, animal feeding value than dried grains.[140] Propionic acid treatment has been used for many years at doses between 0.5% w/w in wheat at 15% moisture and 1.25% w/w in wheat at 30% moisture. There is some evidence that underdosing, whether accidental or deliberate, can result in the growth of fungal strains resistant to propionic acid, which then contribute to the fungal spoilage flora.[81] There is also some evidence that propionic acid and sorbic acids may stimulate aflatoxin production if present at subinhibitory concentrations.[128] More aflatoxin stimulation occurred in laboratory media when dilute (0.05% and 0.1% w/v) propionic or sorbic acid solutions were added to established cultures than when they were added with the fungal inoculum. The concentration of both preservatives in the cultures declined on incubation, indicating that they were metabolized by the *Aspergillus parasiticus* strain studied.

Other chemical treatments to inhibit mold growth or mycotoxin production have been investigated, particularly on high-moisture maize. These include various food grade phosphates,[89] sulfur dioxide with or without added ammonia,[38] ammonium and sodium bicarbonate,[114] sorbic acid,[128] and potassium sorbate with or without propylene glycol.[208] Many different treatments have the potential to inhibit mycotoxin formation, if not mold growth itself. Their disadvantages range from the cost of the treatment, which can be offset against the energy saving from reduced drying, to the corrosive effect of some treatments on the storage silos,[38] which is much more serious.

28.4 PRIMARY PROCESSING AT THE MILL

28.4.1 Cleaning

The mill is the point where cereals are transformed from agricultural commodities to foods or food ingredients. A great deal of physical cleaning takes place in the mill to remove straw and chaff, stones, soil, and metal fragments, which could damage the mill, damaged or ergot-infected grains, seeds other than the cereal grain required, insects, and other foreign matter. The various dry cleaning processes used in modern flour mills have little effect on the microbiological condition of the grain.[41,164,169] They are a considerable advance over the older washing processes, which had the potential to increase the microbiological contamination on the grain.[139] Cleaning processes are described in some detail by Kent and Evers.[73]

28.4.2 Conditioning

In dry milling of wheat, barley, rye, oats, and maize, it is necessary to raise the grain moisture content from that appropriate for safe storage to a higher value that improves the milling performance of the grain. This is achieved by a process called conditioning, or tempering, in which water is added to the grain, which is then held in a conditioning bin for the water to be absorbed. The rate of water addition and the holding time depend on the type of cereal. Holding times for most of the grain for milling would typically be only a few hours, so there is little opportunity for microbial growth to occur. However, conditioning equipment, like the rest of the mill, runs continuously and may only be cleaned weekly or even less frequently. Here, grain lodged in dead spaces may remain at high-moisture content for a prolonged period, promoting microbial growth and even grain sprouting. This grain can contribute to increased counts of molds, yeasts, bacteria, and, in particular, coliform bacteria in the conditioned wheat.[41] Some wheat millers add chlorine to the conditioning water in an attempt to reduce the amount of microbial growth that occurs at this point but little or no reduction of the bacterial count in the conditioned grain is achieved.[169]

28.4.3 Dry Milling

Characteristic features of milling processes are separation of the botanical tissues of the grain (eg, endosperm from pericarp, testa, and embryo) and reduction of the endosperm into flour or grits.[73] Milling may involve either or both operations: rice milling involves only separation, milling of white wheat flour involves separation and size reduction, and milling of wholemeal wheat or rye flours can be merely a size-reduction process.

In dry milling where separation is a key process, as in the production of white wheat flour, the result is flours containing substantially fewer microorganisms than the wheat in the milling grist.[41,151,164,169] This is simply because the microbes are primarily situated on the outside of the grain and are removed with the bran layers.[41,156] The bran is therefore more highly contaminated than the flour,[164] and contains similar or greater numbers of microbes than the milling wheat.[105,164] The microbiological condition of the flour output of the mill, however, remains highly dependent on the condition of the wheat input. This was shown most clearly by Oulsnam in a study of three mills in the UK (Figure 28-4)[126] in which white flour consistently contained approximately 1% of the number of bacteria and 17% of the number of molds and yeasts of the wheat.

28.5 FURTHER PROCESSING

28.5.1 Cereal Meals and Flours

The output from the mill in the form of various meals and flours is mainly used as a raw material for processing into a wide range of cereal products. The total microbial load of cereal flours is highly variable, reflecting the wide range of growing, harvesting, and storage conditions. Standard plate counts between 100 and 10^6 g^{-1} are not unusual, though 10^3 to 10^5 g^{-1} is the core range. Mold counts are a factor of 10 or so lower (Table 28-2),[44,68,69,137] and can also be highly variable.[70] In one study,[111] maize meal contained substantially more molds than either wheat flour or brown rice but whether this is truly representative is not certain.

Occasionally, yeasts may provide the dominant fungal population.[70] Yeasts found in flours from six regions of the US included *Hansenula anomala*, *Pichia farinosa*, *P. burtonii*, *Saccharomyces microellipsoides*, and an unidentified *Candida* species. The yeast-like mold *Aureobasidium pullulans* was also found. *Cryptococcus albidus*, which was the yeast most commonly found in wheat, was not

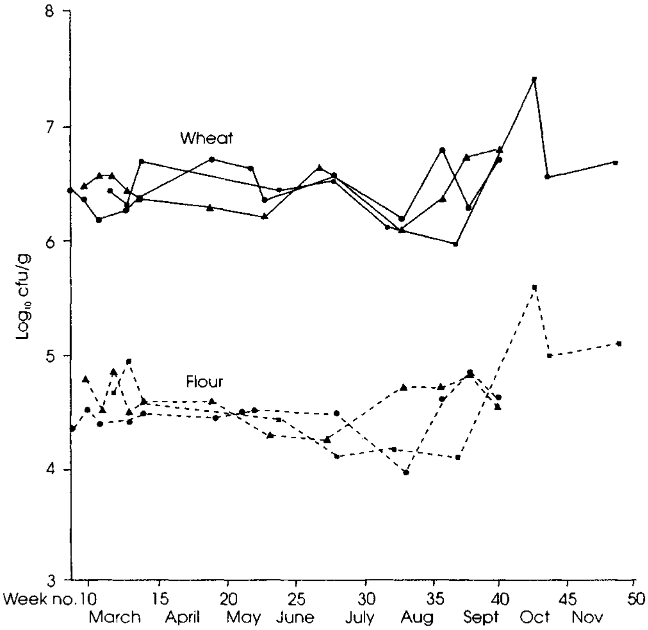

Figure 28-4 Numbers of Bacteria in Wheat Supplied to Three Mills and the White Flour Output from Them. The bacteria were enumerated using pour-plates of plate count agar incubated at 30°C for 3 days. The symbols (■, ●, ▲) each represent a different mill. Each result relates to a separate sampling occasion and hence to the condition of the material passing through the mills at that time. *Source:* Reprinted with permission from M. Oulsnam, Microbiological Condition of Breadmaking Wheat and Flour Taken from Three Mills during 1980, *FMBRA Bulletin,* pp. 179–185, August 1981, © 1981, Campden and Chorleywood Food Research Association.

found in any of the 60 flour samples tested. Overall, 22% of the flour samples yielded yeasts.[83]

Because no actively antimicrobial processes are used, it is not surprising that small numbers of coliforms[7,41,68,69,92] and *Escherichia coli*[68,69,92,149] are readily found in flours and brans,[72] or even that *Salmonella* can be found in a small proportion (0.3% to 2.3%) of flours.[149] This may be considered of little or no significance when the flour is to be used for baking or to make other cooked foods, but it should not be ignored as a potential source of cross-contamination.

In contrast, the presence in flours of spore-forming bacteria may be highly important. *Bacillus cereus* has been observed in a proportion (<10%) of both flours[41,68,69,92] and brans[72] at levels usually of only a few tens per gram. Other mesophilic aerobic spore-forming bacteria are common in flours at levels of up to a few tens per gram[68,69,92] and are a potential cause of spoilage of high a_w products, such as bread. Lactic acid bacteria have been found in over 90% of wheat flours[50,68,69,92] at levels up to 10^4 g^{-1}, though commonly <1,000 g^{-1}, and may contribute to the spoilage potential of uncooked cereal products such as chilled pastry.

Some flours for special purposes are made from grain that has been heat treated using steam to alter the functional properties of the flours. Not surprisingly, these flours contain fewer microorganisms than normal flours. However, in the event of a process breakdown leading to hot, moist grain being held for a prolonged period of time, the number of thermophilic spore-forming bacteria may increase dramatically.

28.5.2 Doughs and Batters

Doughs and batters are an intermediate stage in the manufacture of bread, cakes, pastries, and other cooked cereal products. Essentially, the ground cereal is mixed with water and other required ingredients. The difference between a dough and a batter is one of viscosity: a batter will flow and pour, albeit viscous batters may flow only slowly, but a dough is more resilient. Batters and doughs may be aerated by microbial fermentation, chemically, or not at all. Either may be enriched with sugars, fat, fruit, or other ingredients depending on the final product desired.

Rye and Mixed-Cereal Sourdoughs

The earliest fermented doughs were probably sourdoughs, which developed naturally through growth of lactic acid bacteria and yeasts from the flour. Such spontaneous sourdoughs have become fashionable for production of "organic" rye breads.[136] Sourdoughs retain a dominant position in the manufacture of rye breads because the water-soluble proteins of rye flour do not form gluten. Hence, dough structure relies on pentosans and "mucilages" whose contributions are enhanced in an acid environment; therefore, dough made from flour, comprising more than 20% rye flour, must be acidified to make acceptable bread.[150] The technology of sourdough bread production is described in detail by Spicher.[176] Typically a starter or seed sour is used consisting of a mixture of sourdough bacteria at levels between 2×10^7 and 9×10^{11} g^{-1} and yeasts at 1.7×10^5 to 8×10^6 g^{-1}.[176] The starter may be obtained from a commercial supplier or maintained in the bakery by feeding it with flour and water at intervals. Some bakery-maintained starters could be surprisingly old, possibly 100 years old or more in the case of some San Francisco sourdough starters.[78,182]

Table 28-2 Average Numbers of Some Microorganisms in White Flour Produced in the UK from New-Harvest Wheat (expressed per gram of flour)

Year of Harvest	*No. of Samples Tested*	*Bacteria*[1]	*Molds and Yeasts*[2]	*Spores of Mesophilic Aerobic Bacteria*[3]	*% Samples Containing*	
					Coliform[4] *Bacteria*	Escherichia coli[5]
1988	53	110,000	2,700	56	100	40
1989	43	42,000	1,500	20	72	28

Fourteen different identified species of *Lactobacillus*[99,122,150,176] (Table 28-3) and a range of unidentified *Lactobacillus* spp.[98] have been isolated from starters and sourdoughs as have *Leuconostoc dextranicum*, *Pediococcus* spp., and members of the Enterobacteriaceae.[99]

Eight different identified yeast species have also been isolated from sourdoughs or starters (Table 28-3) including species of *Saccharomyces*,[55,176,182] *Hansenula*,[55] *Pichia*,[176] *Candida*,[150,176] and *Torulopsis*.[176] Although it appears that more bacterial species than yeast species are involved in sourdough fermentations, one should not forget that more attention has historically been paid to the bacteria present in sourdoughs than to their yeasts. There are probably more sourdough yeasts still to be identified.

Yeasted Wheat Doughs

The majority of the world's leavened wheat breads are produced from yeasted doughs containing *Saccharomyces cerevisiae*, added by the baker when mixing the dough. Bakers originally obtained the surplus yeast from their local brewery. However, modern bakers' yeast strains have been developed for desirable characteristics such as rapid gas production and are produced commercially in dedicated fermentation plants. Even so they typically contain some lactic acid bacteria that may be important in flavor development.[181] The technology of bakers' yeast production has been reviewed by several authors.[24,187,188]

Traditional yeasted-dough processes involve a bulk fermentation stage of about 3 hours, although in many small bakeries a 16-hour (overnight) fermentation, known as a sponge, is used as a convenient way to shorten or eliminate the bulk fermenta-

tion. The sponge can be linked to short-time dough processes such as the American sponge and dough method or the Rabinovitch continuous bulk fermentation used in the former USSR.[29] Alternatively, no-time mechanically developed dough processes, such as the Chorleywood Bread Process, may be employed. During the bulk fermentation and sponge and dough processes, flavor compounds, including organic acids and diacetyl, are produced.[181] In mechanically developed doughs, the only fermentation occurs during the short proof time, which may be less than an hour long, when the dough is held warm in a humid atmosphere. During this process step, the yeast produces gas and causes the dough to rise, increasing in volume to give the finished loaf an open crumb structure and light texture.

Yeasted doughs are only slightly acidic, mainly as a result of dissolved carbon dioxide, which is driven off during baking, so they do not provide as much resistance to the growth of undesirable bacteria as sourdoughs. Observations within bread plants, when processes have gone out of control leading to spoilage problems, have shown that *Bacillus* spp. can reach high populations in scrap dough. Unfortunately, the age of the scrap is usually not known, making a judgment on the rate of *Bacillus* growth in the dough impossible. There appear to be no published observations of the growth of pathogenic bacteria in yeasted doughs.

Batters

Simple batters, such as those used for coating foods, consist of little more than cereal flour and water. They have a high a_w and their microflora initially reflects that of the components of the batter. These batters may be held for extended periods, being pumped over the food to be coated with the excess batter recycled. This puts a great deal of emphasis on the need for effective control of batter temperature and maximum holding time. Even in plants operating within the US Food and Drug Administration Good Manufacturing Practice Regulation, batters have been found to contain large numbers of pathogens and other bacteria (up to 5,000 *Staphylococcus aureus* and/or 93,000 *Escherichia coli* per gram).[36] That this does not simply represent contamination of the batter by the food being coated is illustrated by the observation that the bacteriological condition of shrimp in 30 US processing plants improved during processing, but the geometric mean coliform load roughly doubled on battering.[36]

Batters for production of crumpets and certain other hotplate goods contain bakers' yeast, added for flavor and gas production. The potential for *S. aureus* to grow in these is lower than that in simple batters, presumably as a result of competition from the yeast.[127]

Cake batters may contain a wide range of ingredients in addition to cereal flour, for example, fats, egg, sugar, fruit, and others. Hence, the potential range of microbes present, including pathogens, is increased. However, the reduced water activity and relatively short holding time before baking restrict the opportunities for microbial growth.

Other Doughs and Batters

A range of traditional fermentations are used to make products including puto, jeungpyon, and tape (rice cakes from the Philippines,[116] Korea,[71] and Indonesia,[30] respectively); kisra, a Sudanese sorghum flat bread[113]; kenkey, a fermented maize dumpling from Ghana[120]; and ogi, a West African infant food made from maize and sorghum.[153] These products have been developed empirically over generations to suit local conditions and the majority involve primarily a lactic acid fermentation but a detailed understanding of their microbiology is still in its early stages.

28.5.3 Baked Products

Bread

Bread is one of the most important dietary staples in the world and there are a great many national and regional variations on basic types, as well as special breads such as malt loaves, soda breads, milk breads, and fruited breads. In 1991, the value of the Western European bread market was estimated at 230,000 million French francs.[13] Bread is prepared from a dough of cereal flour, which may be unleavened or fermented using yeasts or using a mixture of lactic acid bacteria in a sourdough, and baked. Typical formulations for wheaten bread are shown in Table 28-4.

Microbiologically speaking, the most significant property of bread is its high moisture content (*ca.* 40%) and a_w (*ca.* 0.94–0.97). Bread is baked at oven temperatures between 190° and 260°C (typically about 220°C) but the center crumb temperature does not exceed about 97°C and then only for a few minutes at the end of baking. This makes bread susceptible to growth of molds, which recontaminate the loaf on cooling, and certain bacteria, particularly spore-forming *Bacillus* species that survive the baking process. It has only a short shelf life of 3 to 7 days unless special steps are taken. Few estimates of the losses of bread attributable to mold spoilage in developed countries are available but figures in the region of 1% to 5% have been suggested.[67,75] Mold spoilage

of bread and methods for its control have been reviewed by Legan.[91] Wheat breads, such as those consumed in Western Europe, North America, and elsewhere are usually yeast raised and typically have a pH of about 5.4 to 6.0. These breads are susceptible to bacteriological spoilage caused by *Bacillus* species, known as "rope," as well as to mold growth. In Germany, Scandinavia, and many eastern European countries, rye breads made by a sourdough fermentation process are popular. These breads are much more acid than wheat breads, having pH in the range of 3.5 to 4.8 with a total acidity (sauergrad) in the range of 20 to 8.0 ml.[176] The total acidity is the number of milliliters of 0.1 M NaOH needed to titrate the acid in 10 g of bread to neutrality against a phenolphthalein indicator. If the sourdough fermentation produced only lactic acid this would be equivalent to 2.2% to 0.9% lactic acid.

Despite the fact that bread is distributed at ambient temperature and known to be susceptible to microbial growth, it has a very good public health record. However, bread has been associated with outbreaks of foodborne disease, even in recent years. In 1989, there was an outbreak of hepatitis A in Cambridgeshire, UK, in which the vehicle of transmission for the virus appeared to be unwrapped bread sold from a small shop staffed by an infected food handler.[203] In this case the food vehicle could just as easily have been any other unwrapped food but the case serves as a useful reminder of the need for basic food hygiene, even when handling products not normally considered particularly high risk. There have also been a small number of cases of food poisoning, caused by *Bacillus* species other than *B. cereus*, associated with the consumption of bread spoiled by rope.[25]

Mold Spoilage. Mold spores are killed by the baking process,[79] hence molds spoiling bread gain access during the cooling, slicing, or wrapping operations. The spores are generally considered to spread through the air, with airborne mold spore counts between 50 and 5,000 m^{-3} having been recorded in bakeries.[123,162,175] It is likely that airborne molds are associated, at least in part, with the spread of flour throughout the bakery.[52] Airborne mold spore counts within the bakery are higher when activities such as mixing or cleaning are in progress and when there are more molds in the outside air. High counts of airborne molds are associated with the formation of relatively high numbers of mold colonies on each loaf of bread stored for long enough for spoilage molds to become visible. This relationship breaks down with low airborne counts, suggesting a residual level of contamination from surfaces, equipment, and handling (Figure 28-5).[162]

New strains of molds are continually introduced into bakeries from raw materials and the environment.[207] Nevertheless, conditions within a particular bakery are reflected in the incidence of molds on its products.[121]

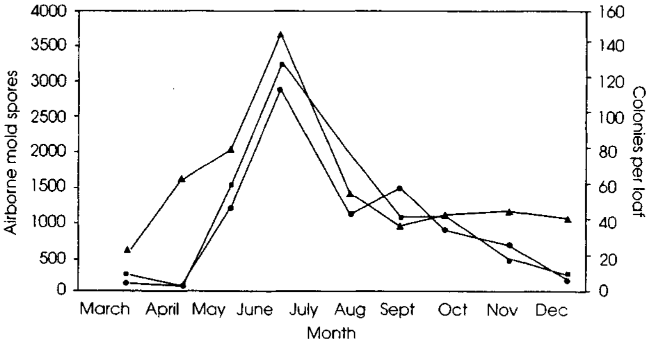

Figure 28-5 Relationship between Airborne Mold Spore Counts and Mold Colony Counts on Bread. ■ Mold spores in air outside the bakery, ● mold spores in air in the bread cooling area, ▲ colonies forming on bread. The bread was stored at 27°C for 6 days before examination. *Source:* Reprinted with permission from D.A.L. Seiler, Counting Moulds in the Bakery Atmosphere, 1. Seasonal Fluctuations, *FMBRA Bulletin*, pp. 54–58, April 1972, © 1972, Campden and Chorleywood Food Research Association.

The most common bread spoilage molds are *Penicillium* spp.,[2,63,121,131,176,177] although *Aspergillus* spp. may be more important in tropical countries.[129] On loaves of yeast-raised, wheat breads made and stored in the UK until visibly moldy, Odell[121] observed *Penicillium* spp. on 90% to 100% of loaves, *Aspergillus* and *Cladosporium* spp. on about half the loaves, and Mucorales on 20% of the loaves. The incidence of the different genera was constant throughout the year. The type of spoilage appearing first on sourdough rye breads in Germany was dominated by *Penicillium roquefortii* (91.4% of 437 loaves stored), other penicillia (3.4%), and *Aspergillus* or *Eurotium* spp. (3.4%).[177]

Mycotoxigenic species of *Aspergillus* and *Penicillium* have been isolated from bread.[23,185,197] Moreover, mycotoxins including citrinin,[144] aflatoxins B_1, B_2, G_1, G_2, and M_1,[145,146] ochratoxin A,[145] and a range of *Alternaria* toxins[147] have been detected in inoculated breads. However, even in inoculated breads not all mycotoxigenic molds are able to produce toxin.[144] Some mycotoxins, eg, patulin and penicillic acid, are inactivated in the presence of bread proteins,[124,144,148] and mycotoxins do not readily diffuse through bread in the absence of hyphal ramification.[145] Moreover, mycotoxins are only detected after bread shows visible growth of molds. These factors contribute to the low risk to consumers in developed countries from mycotoxins in bread. The picture is not so clear in developing countries. There is a statistical correlation between cirrhosis of the liver and consumption of moldy steamed bread in China[22] but other risk factors such as hepatitis and pipe smoking were also identified.

"Rope" and Other Bacterial Spoilage. The spoilage condition of bread known as "rope" is caused by the growth of *Bacillus* spp. The rope organism was first identified as *B. mesentericus* by Watkins in 1906[204] but later renamed as *B. subtilis*. Subsequently, other *Bacillus* spp. have been identified in ropy bread, especially *B. licheniformis* and occasionally *B. pumilis*, *B. megaterium*, and *B. cereus*.[77]

Bacillus spores are present in flour[11,64,68,69,74,92,97] and other ingredients[64] and may also be found on bakery equipment,[201] particularly when hygiene does not receive enough attention. They are resistant to the heat process given in baking and survive in the center of the loaf. Once the bread has cooled, the spores germinate and grow. Rope is noticed first by its odor, usually described as "fruity" or "sweet" like overripe melons or pineapple but the description is rather subjective. It has been described as "objectionable," resembling "a mixture of rotting fruit and bad cheese."[45] As the condition develops, the center of the loaf becomes sticky until fine threads can be drawn from it. The crumb subsequently darkens and, once the condition becomes extremely advanced, may collapse completely.

Rope is of limited economic significance in temperate countries, where growth of the bacilli is constrained by a combination of preservatives and moderate ambient temperature allowing molds to become visible before rope spoilage develops. Nevertheless, outbreaks causing losses to individual bakeries are experienced during most summers. However, in hot countries such as South Africa, rope is a significant cause of loss.[77] Moreover, it has been recognized in recent years that *B. subtilis* and *B. licheniformis* both have the potential to produce a toxin-mediated food poisoning.[196] Hence, even in temperate countries this adds emphasis to the need to prevent rope spoilage. Rope is not a problem in sourdough rye breads where it is prevented by the acidity of the bread.

"Bleeding bread" is a spoilage condition caused by growth of *Serratia marcescens* when ambient temperatures are high. This results in production of red or pink pigment such that heavily affected bread appears to bleed. Early examples were attributed to miracles.[183] Bleeding bread is rare nowadays, presumably as a result of improved bakery hygiene, combined with the use of preservatives.

Preservation. Bread preservation aims to delay the onset of both mold and rope spoilage, reducing losses and giving extra shelf life to the product. The principal bread preservatives in use worldwide are propionic, sorbic, and acetic acids as well as certain of their salts. Background information about these materials is given by Lueck[102] and Doores[35] and a detailed review of sorbates has been given by Sofos and Busta.[174] The use of preservatives is regulated by law in many countries and reference should always be made to the appropriate legislation when deciding on a preservative regime. In the UK, the preservative of choice for all bread for many years has been calcium propionate, but recent legislation has restricted its use to prepacked breads.[5]

Propionates are commonly used in bread as 0.1% propionic acid or 0.2% calcium propionate based on flour weight,[91] which gives about one extra day's life to yeasted wheat breads. These materials inhibit both molds and rope but also reduce the activity of the yeasts in the dough, necessitating an increased yeast level, longer holding (proof) time for the yeasts to produce gas, or use of an improver such as ascorbic acid to avoid loss of loaf volume.[91]

Sorbates have greater antimold activity on a weight-for-weight basis than propionates. Hence, they cause greater inhibition of the yeast. They can also make doughs very sticky and difficult to process.[91] Sorbates are widely used in German sourdough breads[177,178] at levels not exceeding 0.2% of final product weight. Presumably, the longer fermentation times and mixed ferment of yeast and lactic acid bacteria make the inhibition of yeast activity less noticeable in these products. In the US, breads have been successfully preserved against molds using a spray of sorbic acid[58] or potassium sorbate[75] applied after baking.

Acetic acid, in the form of vinegar, is used traditionally to prevent rope.[9] A concentration of 0.1% to 0.2% w/w of acetic acid in flour is effective against rope but has a limited effect on molds. At higher levels, the odor of vinegar becomes quite noticeable.[91] Sodium diacetate (sodium hydrogen acetate) at 0.3% w/w of flour will retard molds under most practical conditions.[53] Calcium acetate at 0.3% w/w of flour was more effective than 0.2% calcium propionate for inhibiting rope.[77]

Ethanol, where permitted, increases the mold-free life of bread when used at concentrations between 0.5% and 3.5% applied after baking.[51,136,167,171,202] The benefit is increased because it is one of the few materials that can also retard staling.

There has been considerable interest in ingredients with "natural" antimold properties. Dried, cultured wheat flour containing lactic and acetic acids has been used in the US.[117] Also in the US, raisins[37,85,209] and prune juice concentrates[152] have been shown to extend the mold-free life of bread. Hydroxymethyl furfurals formed from the fruit sugars during baking, together with naturally occurring tartaric and propionic acids, probably account for the antimold activity, though this has yet to be proven.

Modification of the atmosphere around the product using a high concentration of carbon dioxide gas retards the growth of molds on bread and other baked products (Figure 28-6).[21,34,80,94,103,167,168,173,202] Mold-free life can be increased by 100%, 200%, and 300% in atmospheres containing respectively 40%, 60%, and 90% CO_2 by volume. However, CO_2 at atmospheric pressure does not inhibit yeasts to any significant extent. Hence, bread packed in CO_2 atmospheres shows a higher incidence of the spoilage type known as "chalk mold," caused by yeasts that show mycelial or pseudomycelial growth, especially *Pichia burtonii* and *Saccharomycopsis fibuligera*. CO_2 does not prevent the growth of *Bacillus licheniformis*; therefore, in time, CO_2-packed breads may develop high populations of *B. licheniformis* or even display signs of rope spoilage, particularly in hot weather. Questions have also been raised about the potential for anaerobic spore-forming bacteria to grow in CO_2-packed breads. During the long history of these products in the marketplace, there have been no recorded problems of this type, but the factors preventing them are not clear.

Gas-packaging equipment is expensive. Hence, breads packed in CO_2 tend to be high-value niche products such as special dietary breads, ethnic breads, or long-life part-baked breads where reheating by the consumer is used to reverse the effects of staling. Another approach to atmosphere control, requiring less expensive equipment, is to use oxygen-absorbing materials such as "Ageless" (Mitsubishi Gas Chemical Company Inc., Tokyo, Japan) or the ATCO oxygen absorber (ATCO S.A., Caen, France) to reduce the oxygen concentration in the pack.[84,138,173] Powers and Berkowitz[138] showed that this method can keep bread free of mold growth for over a year; however, they did not investigate the potential for growth of anaerobic spore-formers.

Legan, Mould spoilage of bread: the problem and some solutions, Copyright 1993, pages 33–53, with kind permission from Elsevier Science Ltd, The Boulevard, Langford Lane, Kidlington, OX5 1GB, UK.

A model for growth of *Clostridium botulinum* in cooked vacuum packed potatoes predicts that growth and toxin production can occur at 25°C, pH 5.50, and a_w 0.965,[33] conditions that could easily be achieved in bread products made from yeasted doughs. It is more difficult to compare the redox potential in cooked vacuum packed potatoes with that of breads in modified atmosphere packs because measuring the redox potential inside a food product is fraught with many difficulties. In an analysis of 2,000 outbreaks of botulism between 1951 and 1989 (most after 1980), no involvement of flour-based products was found.[65] Thus, there is no evidence for a real botulism hazard from bread products packed in modified atmospheres, perhaps because the packs have contained sufficient residual oxygen to inhibit growth and toxin formation. High-speed gas-flushing equipment typically achieves 90% atmosphere replacement when packaging bread and cakes, implying a residual oxygen concentration of about 2%, whereas residual oxygen concentrations well below 1% can be achieved in vacuum packs. Nevertheless, the factor(s) governing the safety of bread products packed in modified atmospheres are not currently well understood. Not enough is known about how interactions between residual oxygen concentration, pH, and water activity prevent the growth of *C. botulinum*.[205] It is not safe to assume that merely because some products have not caused botulism in the past they will not do so in future.[1]

As with other food products, the best way to ensure the safety of cereal products in modified atmosphere packaging is to adopt a hazard analysis critical control point (HACCP) approach.[94,112] *Clostridium botulinum* would not be the only concern of a HACCP system applied to bread products packed in modified atmospheres but it may easily be overlooked. The minimum a_w for growth of *C. botulinum* types A and B is 0.94.[49] It is difficult to consistently manufacture a palatable bread with an a_w lower than this, so a combination of pH, a_w, and preservatives is most likely to be used to prevent the growth of *C. botulinum* in these products.

Flour Confectionery

Flour confectionery (eg, cakes, pastries, puddings) includes an intriguingly wide range of microbiological problems. At one extreme, the products can be extremely perishable, usually as a result of the inclusion of a filling such as cream or custard with a high a_w. Such products can support bacterial growth and have been associated with outbreaks of food poisoning. At the other extreme the products may be stable for months or years as a result of intermediate or low a_w.

Association with Food Poisoning. Out of 2,226 outbreaks of food poisoning in the US between 1973 and 1987, 51 were attributed to bakery products. The split between different types of baked goods was not reported, nor was the contribution of any filling.[14] It is clear, however, that cakes and pastries with perishable fillings, such as cream or custard, have been the cause of food poisoning. These products are often produced in small craft or artisanal bakeries where a high proportion of hand operations is involved in filling and finishing the product. Therefore, it is not surprising that in surveys published since 1983, coliforms[107] and *E. coli*[61,133] have been observed in up to 30% of cakes and pastries, particularly those filled with cream. The incidence of *E. coli* was worse in dairy cream slices (23 out of 92 products) than in nondairy cream slices (12 out of 101 products).[61] *Staphylococcus aureus* and *B. cereus* have also been found in between 4.0% and 25% of cream-filled pastries.[61] Even in reasonably large plant operations operated to US good manufacturing practice guidelines, coliforms were detected in nearly 30% of cream pie fillings just prior to freezing.[157] However, the numbers present were low, with 97.5% of samples yielding <150 g^{-1} and the incidence of *E. coli* was close to zero.

An example of outbreaks associated with these products is an outbreak of food poisoning in 1983 linked to custard-filled vanilla slices; 36 people suffered diarrhea and vomiting in 15 minutes to 3 hours after consuming the product.[43] *S. aureus, B. cereus,* and *B. subtilis* were all isolated from vanilla slices taken from the same batch as those causing the outbreak. The primary cause of illness was attributed to *S. aureus* enterotoxin A, but the rapid onset of illness suggested that *B. subtilis* or *B. cereus* toxin(s) may also have been involved. In another outbreak in 1991, 17 people contracted *Salmonella enteritidis* phage-type 4 food poisoning from custard slices from a small bakery.[10] The custard had been made with fresh shell eggs and had not been properly cooked.

The potential for pathogens to grow in cakes and pastries, particularly those with cream or custard fillings and/or high water activity, and cause illness in consumers emphasizes the need to operate strict hygienic controls during manufacture of these products. Moreover, it demonstrates the need to take steps to control growth of organisms between manufacture and consumption of the products. This is most easily done by chilled or frozen storage and display. Unfortunately, chill temperatures may accelerate the rate at which the cake or pastry stales. In UK law, perishable foods at or in food premises are now required to be kept below 8°C, although there is a derogation to allow the sale of such foods at room temperature for a maximum of 4 hours after production, after which they must be destroyed.[6] As a result it is only in small craft bakeries that it is still possible to buy custards, sandwiches, and similar products at ambient temperatures.

Spoilage. Flour confectionery products with high a_w may be susceptible to bacterial spoilage, the most familiar manifestation being the souring of dairy cream fillings by lactic acid bacteria. Similar spoilage may occur in raw pastry during chilled storage, particularly if the numbers of lactic acid bacteria are allowed to increase during manufacture, for example, by poor control of recycled trimmings or poor temperature control.

More commonly one thinks of "ambient-stable" flour confectionery products. These are expected to have shelf lives of anything from a few days to several months and are generally very safe because their a_w is too low to support bacterial growth. In most flour confectionery products the primary factor limiting shelf life is mold or yeast growth. However, rancidity, staling, drying out, or softening due to moisture gain are all factors capable of limiting the life of these products.

The rate at which molds or yeasts spoil flour confectionery is defined in the first instance by the a_w of the product.[160,163,165] Typical a_w and spoilage for a range of products is given in Table 28-5. Other important product characteristics are pH and type and concentration of preservatives. Environmental conditions including temperature and atmosphere around the product will also influence the rate of spoilage.

Mold or yeast spoilage of flour confectionery could manifest itself in several ways[93]:

1. As typical mold colonies, especially *Penicillium* or *Aspergillus* spp., but in products with lower a_w, xerotolerant molds, including *Eurotium* spp. and *Wallemia sebi*, become more common.
2. As bubbling in jams, fondants, or fruit fillings or as pitting or cracking of icings as a result of the pressure of carbon dioxide gas formed by yeast fermentation. Fermentation also produces alcohol and other compounds with strong odors. For example, *Pichia anomala* can produce ethyl acetate, which may give the impression of a product suffering from a chemical adulteration. Another yeast, *Pichia burtonii*, has been known to produce styrene when fermenting spiced syrup containing cinnamon[27,96,132] as used for glazing hot-cross buns.
3. As low white or off-white "dusty" growth of one of a number of "pseudomycelial" yeasts such as *Candida guilliermondii, C. parapsilosis, Debaromyces hansenii, Pichia anomala, P. burtonii,* or *Saccharomycopsis fibuligera* on the product surface. This is particularly visible on the surface of dark products and is known as "chalk-mold" because of its resemblance to a sprinkling of chalk dust.[96] It is more frequently seen on breads than on flour confectionery.

In products with a_w below 0.8 the spoilage mycoflora becomes restricted to the more xerophilic molds and osmophilic yeasts. Below a_w 0.7, flour confectionery can, for most practical purposes, be considered safe from spoilage, provided that condensation is avoided as it can lead to localized regions of higher a_w. However, there are a few species able to grow at a lower a_w, notably the yeast *Zygosaccharomyces rouxii*, minimum a_w 0.65,[184] and the mold *Xeromyces bisporus*, minimum a_w 0.61.[134] Hence, on rare occasions, molds or yeast may spoil flour confectionery with a_w lower than 0.7. Products with a_w below 0.6, such as biscuits and crackers, are not at risk from microbiological spoilage provided that they are packaged and stored to prevent moisture migration from the environment or within the product leading to a general or localized increase in a_w.

Table 28-5 Water Activity of a Range of "Cereal" Products and the Principal Type(s) of Spoilage Associated with Them

a_w	*Products*	*Spoilage Types*
0.99	Creams, custards	Bacterial souring
0.95–0.98	Breads, hotplate goods	Bacterial spoilage, eg, "rope"; mold growth and "chalk molds"
0.90–0.95	Moist cakes, eg, carrot cake, some breads	Mold and yeast, bacterial spoilage, eg, "rope"
0.8–0.89	Plain cakes	Molds and yeasts
0.7–0.79	Fruited cakes	Xerophilic molds and osmophilic yeasts
0.6–0.69	Some dried fruits or fruited cakes	Specialized xerophilic molds and osmophilic yeasts
<0.60	Biscuits, chocolate, some dried fruits	No microbiological spoilage

Water activity can be used to predict the likely shelf life of a product. In the 1960s, Seiler[160] demonstrated that the shelf life of cake increases logarithmically as the a_w decreases (Figure 28-7). This relationship is widely used in the baking industry to estimate the mold-free shelf life of new products, reducing the need for extended storage trials. It is also used during new product development to identify the a_w needed to achieve the desired mold-free shelf life.

The rate at which yeasts spoil flour confectionery is also influenced by a_w. Fermentative spoilage problems are less common than mold spoilage, but at a given a_w fermentation tends to occur more quickly than mold spoilage. Since the materials that are most susceptible to fermentative spoilage, such as jams and icings, are used as fillings and coatings, this is very important because moisture migration from the product crumb to the filling can increase its a_w and reduce its expected fermentation-free life.

Product acidity can influence the rate of microbial growth, however, flour confectionery products are primarily spoiled by molds or yeasts, which tolerate a wide pH range. In these products, pH becomes most important because of its influence on the activity of any preservatives that may be included.

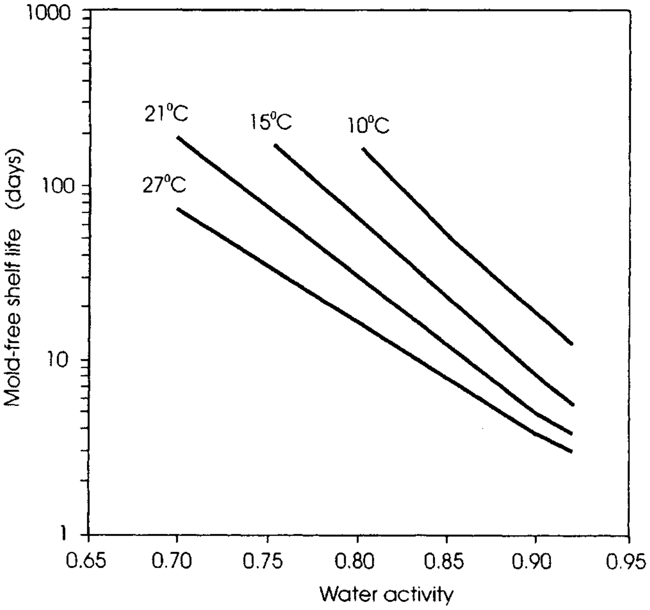

Figure 28-7 The Relationship between the a_w of a Cake and Its Mold-Free Shelf Life at Different Temperatures. The a_w was determined by the proportion of sugars, glycerol, salt, and water (from all sources including other ingredients) in the recipe. *Source:* Data from D.A.L. Seiler, Microbiological Spoilage of Bakery Products, *Swiss Food,* Vol. 3, pp. 42–44, © 1981.

Preservation Methods. The preservatives used most commonly for flour confectionery products are propionic acid and sorbic acid as well as certain of their salts. The maximum concentration of these preservatives permitted in the UK have recently been increased to 0.2% w/w of finished product (calculated as the acid)[5] for most products in which they are permitted. Since both are organic acids (or their salts), their antimicrobial action depends largely on the concentration of undissociated acid (or salt) present. The percentage of undissociated acid increases as the pH decreases; therefore the effect of these preservatives will depend on the pH of the product (Figure 28-8). Dramatic increases in mold-free life are theoretically possible, particularly in products with low a_w. However, high concentrations of preservative can cause off-odors and flavors within the product. It is difficult to generalize about the concentration of sorbate which a consumer might notice because of the possible masking effects of other flavors in the product. A level calculated to give a 50% increase in mold-free shelf life rarely causes such problems and the maximum permitted

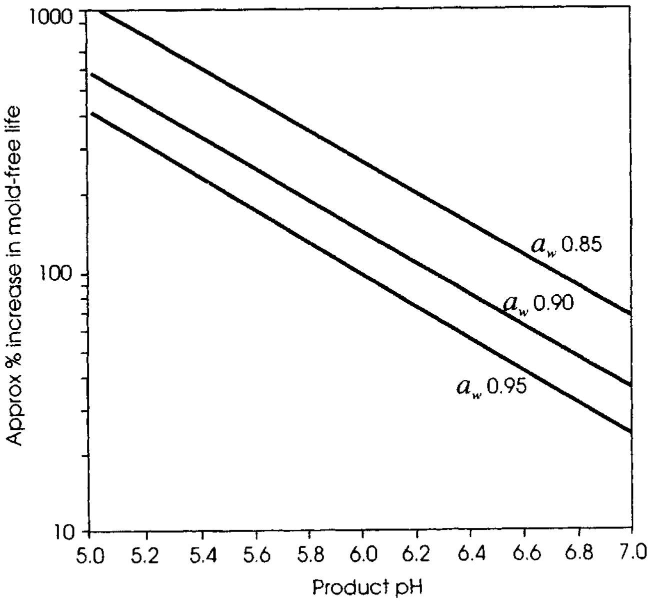

Figure 28-8 Approximate % Increase in the Mold-Free Shelf Life of Cake with Different pH Values Treated with Sorbic Acid at 1000 mg kg^{-1} Compared with a Control Cake of the Same a_w Containing No Sorbic Acid, pH Not Stated. *Source:* Data from D.A.L. Seiler, The Microbial Content of Wheat and Flour, *FMBRA Bulletin,* pp. 26–36, February 1978, © 1978, Campden and Chorleywood Food Research Association.

concentration of 0.2% sorbic acid may prove acceptable even when this will give a much greater than 50% increase in mold-free life. Nevertheless, sensory evaluation of a test batch of product is always recommended.

Modified atmosphere packaging using various gas mixtures has been shown to extend the shelf life of flour confectionery products. Use of 100% carbon dioxide around products with a_w below 0.90 has increased the mold-free life to up to five times that in air packs provided that loss of gas is prevented (Figure 28-9).[170]

28.5.4 Pastas

Pastas are prepared from durum wheat semolina (coarse particles of endosperm) or flour mixed with water into a very stiff dough and extruded through dies to give the final product shape. The dough contains around 30% moisture and may contain egg or other ingredients such as spinach, tomato, or other vegetables. On an industrial scale, pasta is usually mixed under vacuum in a continuous mixer, which may run for up to a week for nonegg pastas.[62]

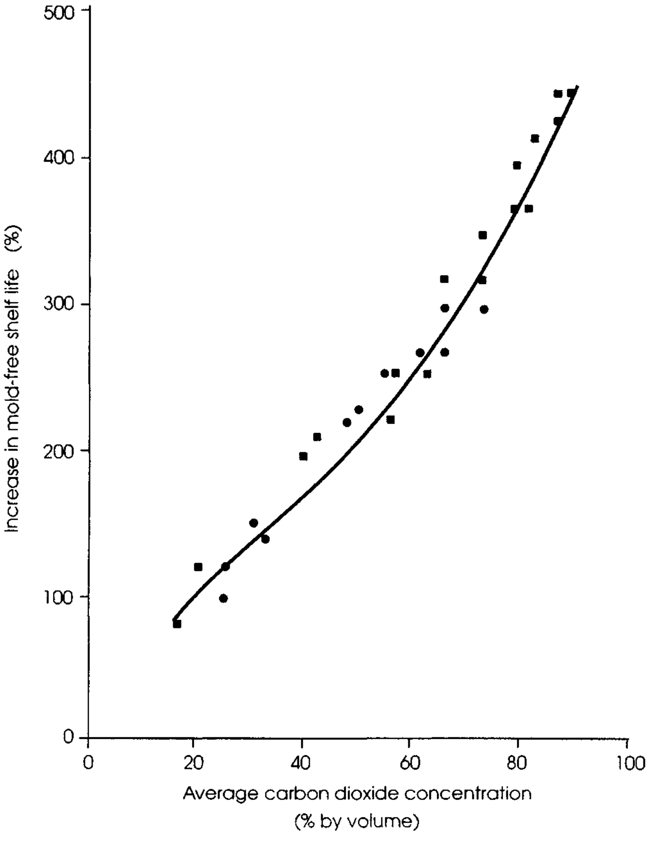

Figure 28-9 The Effect of Packaging in CO_2 on the Mold-Free Shelf Life of Cake. *Source:* Data from D.A.L. Seiler, Controlled Atmosphere Packaging for Preserving Bakery Products, *FMBRA Bulletin*, pp. 48–59, April 1984, © 1984, Campden and Chorleywood Food Research Association.

Dried Pastas

Most pasta is dried to a moisture content of 10% to 12%, which produces a product stable at ambient temperatures for very long periods. However, if dried pasta becomes moist, perhaps as a result of poor storage, it becomes susceptible to microbial spoilage. The initial microflora of dried pasta is variable, with recorded bacterial counts ranging between 10^3 g^{-1} and over 10^7 g^{-1},[40] and a range of molds including *Penicillium* and *Aspergillus* spp. are commonly present. Some pasta is sold fresh, sometimes filled with meat or cheese, and increasing amounts are sold from chilled display units after "pasteurization" and/or vacuum or modified atmosphere packaging.[54,190] Hence, there is potential for a wide range of microbiological problems.

The pathogen particularly associated with pasta is *Staphylococcus aureus*. Over 4% of Canadian-produced, dried, nonegg pastas, and over 5% of dried egg pastas, contained more than 25 *S. aureus* g^{-1}.[142] High concentrations of staphylococcal enterotoxin have been found in dried lasagna, which caused food poisoning in several European countries[56] and enterotoxin has been detected in dried pasta after storage for a year.[141] Clearly, it is essential to control *S. aureus* during pasta production and drying in order to protect the consumer. One of the difficulties to be overcome is that *S. aureus* is tolerant of lower a_w than other bacterial pathogens. It has been reported as multiplying in drying pasta until the a_w was below 0.86.[194] Therefore, drying needs to take place as quickly as possible consistent with avoiding stress-cracking of the product. Even when drying at the relatively low temperatures of 35° or 40°C, *S. aureus* did not produce enterotoxin in inoculated pasta when initial levels were 10^5 g^{-1} or lower[125] so the hygiene of the process prior to drying is clearly an important contributor to product safety.

Salmonella species derived from egg have been recorded as surviving the drying process for pasta and then remaining viable for several months in the final product.[40] *Salmonella typhimurium* and *S. infantis* inoculated into pasta before drying were still detectable after a year.[141] These organisms would be killed when the pasta was cooked, but most consumers would not consider dried pasta to be a risky material and are unlikely to handle it in such a way as to prevent cross-contamination to other foods. Therefore, there is a considerable responsibility on the manufacturer to ensure that *Salmonella* does not gain access to the product, in particular by using only pasteurized egg in pasta doughs.

Clostridium perfringens has also been reported in dried pasta.[40] However, pasta is unlikely to be a significant source of this organism under normal circumstances.

Fresh Pastas

Staphylococcus aureus can be even more of a problem in "fresh" (not dried) pastas than it is in dried. The a_w of fresh pasta is high (0.92–0.99), the higher values being associated with pastas filled with meat or cheese, eg, ravioli.[54] Trovatelli et al.[190] found more than 500 *S. aureus* g^{-1} in over 25% of factory-made pastas in the Bologna region of Italy with 14.3% containing over 10^4 g^{-1}. A similar proportion of pastas from small producers contained over 500 g^{-1}, but only 7.7% contained over 10^4 g^{-1}.[190] In another study, 12% of fresh pastas contained 10^2 to 10^5 *S. aureus* g^{-1}.[130] During storage at 5°C, the numbers declined over 4 weeks and no enterotoxin was detected, but after 4 weeks at 16°C, 22% of the samples contained 10^3–10^7 *S. aureus* g^{-1}, and 8% contained enterotoxin. This demonstrates quite clearly the importance of good cold storage during distribution and display of fresh pastas.

Other microbes are found in fresh pastas, potentially in large numbers. In a study of industrial nonegg pastas, nearly 70% of the samples of simple pastas (tagliatelle, spaghetti, and fettucini) tested gave aerobic plate counts $>10^6$ g^{-1} (the Italian legal maximum).[106] An even higher proportion (87%) of samples of filled pastas had aerobic plate counts $>10^6$ g^{-1}. In contrast, just under 30% of samples of egg pasta from small manufacturers had total viable counts of 10^6 g^{-1} or more.[104] Fecal coliforms in nonegg pastas were detected at a level greater than 10^3 g^{-1} in 17% of filled and 3% of simple pastas.[106] An even higher proportion of fresh pastas produced by small manufacturers contained $>10^3$ fecal coliforms g^{-1} (5% to 20% between 1984 and 1986[135]). Bacterial species identified among coliforms isolated from pastas include *Klebsiella oxytoca, Klebsiella pneumoniae, Enterobacter cloacae, Enterobacter agglomerans, Escherichia coli, Serratia* spp., *Providencia alcalifaciens,* and *Hafnia alvei.*[48]

"Long-Life" Pastas

Fresh pastas are increasingly being packed under vacuum or modified atmospheres to extend the shelf life of the product and provide the consumer with a convenient, attractive product. These products are often distributed in chill conditions. The technologies can certainly delay the onset of mold spoilage.[32] Fresh pastas packed in air and stored at 4°C showed visible mold growth after 6 to 7 days, whereas in vacuum packaging no mold growth occurred within 14 days. Bacteriological spoilage may occur, however, particularly under temperature-abuse conditions. One curious manifestation of bacteriological spoilage was a pink discoloration of vacuum packaged gnocchi held at 8°C caused by growth of *Bacillus polymyxa.*[180]

High aerobic bacterial counts (10^6 to 10^7 g^{-1}) have been detected in vacuum packed pastas.[8] In the same study, aerobic mesophilic spore counts of 10^3 to 10^4 g^{-1} were obtained but no *S. aureus* was detected. In contrast, in a Canadian study, 17.5% of plain and 33.7% of filled pastas in modified atmosphere packs contained detectable levels of *S. aureus.*[42]

In an investigation of the ability of proteolytic strains of *Clostridium botulinum* to multiply and form toxin in pasta, 6.6×10^2 spores g^{-1} were inoculated into pastas with a range of a_w, which were then packed in atmospheres of N_2 or N_2 and CO_2.[54] Toxin was formed in products with an a_w higher than 0.95 stored at 30°C. Most of the flat noodles were at an a_w below the limit that allowed growth of proteolytic *C. botulinum*, but most of the filled pastas had an a_w higher than 0.95. Admittedly, this study was under conditions of severe temperature abuse but it illustrates well the need to understand the effect of process or packaging changes on the safety of traditional products.

Cooked Pastas

S. aureus can grow well on cooked pasta. For example, in cooked egg pasta inoculated with approximately 100 *S. aureus* g^{-1}, production of staphylococcal enterotoxin A occurred in 3 days at 15°C and only 1 day at 25°C.[56] Hence, cooked pasta needs to be treated with some care to minimize the opportunities for contamination with *S. aureus* and should be maintained in chilled conditions to retard its growth. Holding hot (>63°C) prior to serving would be an alternative in a catering situation.

28.6 CONCLUDING REMARKS

Cereals and cereal products provide the staple food source for a large proportion of the world's population. Cereals are relatively cheap, nutritious, palatable, and versatile foodstuffs. Traditional technologies for storing and processing cereals give products with a record so good, overall, that their safety is taken for granted by the consumer. This compares favorably with other food groups, particularly meat, poultry, eggs, and dairy products: all perishable foods that readily support microbial growth and have a history of causing food poisoning when not stored or prepared correctly. It would be unwise, however, to assume that there are no microbiological hazards associated with cereal-based foods. Those currently known or suspected have been reviewed in this chapter but there is much still to discover.

Little is known about the bacteriology of cereals relative to the wealth of literature relating to fungi and mycotoxins. The range of bacteria, including pathogens, spoilage organisms, and commensals typically associated with different cereals, is not well documented. The source of pathogens found in cereals has not been rigorously identified and the role (if any) of cereal meals and flours as vehicles for the spread of pathogens is not well understood. With the wider implementation of HACCP systems in the food industry, long-standing assumptions about cereal products are being questioned and the answers are not always available.

"Industrial" bread baking as practiced in the UK, US, and other developed countries has been honed to very high levels of efficiency with the emphasis on cost and product appearance. More consideration is now being given to flavor, and the use of mixed sourdoughs, modified yeast cultures, and fermentation technology to this end is beginning to be explored.

Cereal products similar to traditional items but intended to have longer life (and therefore be more convenient) have been developed over several years. Over the same period, products with "moister eating" character and fewer preservatives have been produced. Both developments have made use of technologies not traditionally associated with cereal foods, for example, modified atmosphere packaging and chilled storage. There are two challenges here. The first is to identify correctly the factors that govern the safety of the new products and the second is to educate consumers to recognize the different handling and storage conditions that may be required. There remain plenty of questions for cereal microbiologists to explore, and the activities of the food technologists are likely to generate more questions, not fewer, in the future.

29.1 INTRODUCTION

Yellow fat products are used for many purposes including spreading on bread, cooking and baking, and as topping on meals or meal components. Classical examples are butter and margarine; water-in-oil emulsions that contain at least 80% fat (w/w). Nutritional recommendations to limit the amount of fat, in particular saturated fats, in the diet have resulted in a decline of the consumption of yellow fat spreads in developed countries and a relative shift to low-fat products. The consumption of butter and related products seems to have stabilized, whereas the consumption of margarines and related products is declining.[36,46]

Butter is an ancient dairy food in which the milk fat has been concentrated. Salt and starter cultures may be added. Butter was originally made directly from milk on a small scale. Its factory production dates from about 1850.[78] Most changes in butter manufacture have concerned the process design, and new types of butter-making processes have been introduced.[33] The composition of butter is subject to stringent regulations and thus has not changed much over the years. Low-fat variants of butter have recently appeared on the market, together with products based on mixtures of butter/butter fat and vegetable fat blends (melanges),[52] which may be produced by a typical butter and/or margarine process and can be either full-fat, medium-fat, or low-fat.

Margarines and related products are made of water, oil, and fat to which ingredients such as milk or milk products, salt, and thickeners may be added depending on the type of product. Margarine was developed during the 19th century as an alternative to butter, which at the time was in very limited supply. The oils and fats used for margarine manufacturing have undergone major changes since the production of the first margarine in 1869. Animal fats, such as lard, tallow, and fish oil, were used in margarine production until the early 20th century when they were replaced by vegetable oils and fats, eg, coconut oil, cottonseed oil, and, more recently, by soya oil and sunflower oil. Fat blends are designed so that they will meet requirements such as spreadability at refrigerator temperature, cooking or baking performance, and keepability. Since the mid-1960s, several margarines have been developed based on fat blends high in polyunsaturated acids. Another important trend is the development of products with a low fat content for spreading on bread. The first product containing 40% fat was introduced in 1964 in the United States (US), and the first product containing 20% fat in 1988 in the United Kingdom (UK). Products with fat levels from 20% to 80% have now gained widespread acceptance.[42,51,52,56,57] Recently, products with fat levels as low as 3% have successfully been introduced in the US, UK, and The Netherlands. In addition, products have been developed for specific purposes, eg, liquid, squeezable margarines for cooking and baking.

Yellow fat products manufactured in developed countries are generally of a very good microbiological quality. Fat can act as a barrier to microbial growth, and for this reason systems with a continuous fat phase are usually much more stable than systems with a continuous aqueous phase. The decrease in fat content in many products can have consequences for the microbiological stability of these products, as they often consist of a water-in-oil emulsion with coarser water droplet sizes. In addition, a higher water content results in lower levels of salt in the aqueous phase. There are, however, no indications that industrially produced yellow fat products play a significant role in foodborne disease, despite the recent case of contamination of butter with *Listeria monocytogenes*.[50] This is probably due to a continually increased attention to hygiene during manufacturing,[19,35,48] to the quality of raw materials, and to the pasteurization conditions applied, which ensure absence of vegetative pathogens. It remains necessary, however, to pay considerable attention to the microbiology of yellow fat spreads, especially of new products and processes.[44]

29.2 BUTTER

29.2.1 Composition and Structure

Composition

The composition of butter is strictly regulated in many countries. Butter consists of at least 80% milk fat, a small amount of nonfat milk solids, salt (sodium chloride if any), and water. A lactic starter culture, colors, and neutralizing agents may be used during manufacture. It is normally not permitted to add preservatives, other than salt, or anti-oxidants to butter.[9,59] In Western Europe butter and butter-like products are described as: "Products in the form of a solid malleable emulsion, principally of the water-in-oil type, derived exclusively from milk and/or certain milk products, for which the fat is the essential constituent of value. However, other substances necessary for their manufacture may be added, provided those substances are not used for the purpose of replacing, either in whole or in part, any milk constituents."[17] Butter is more specifically defined as: "The product with a milk fat content of not less than 80% but less than 90%, a maximum water content of 16% and a maximum dry non-fat milk-material content of 2%."[17]

Most countries in Europe favor cultured butter, which is unsalted, or at most salted to a level not exceeding 0.5% (w/w). In the English-speaking countries of the world (eg, UK, US, and Australia)[34,59] and in Japan and India[34] sweet cream butter is sold almost exclusively, often with 1.5% to 2% (w/w) salt. Finally, unsalted sweet cream butter is preferred in Czechnia and Slovakia.[34] Cultured butter contains lactic acid in place of lactose and usually has, if not neutralized, a pH of 4.6–5.3. In microbiological terms, the aqueous phase of sweet, unsalted butter is much more unstable than that of salted or cultured butter.

Structure

Butter is, like margarine, a fat-continuous (water-in-oil) emulsion in which the water is compartmentalized in small droplets. The microbial stability of butter depends largely on a proper water dispersion. If the water is dispersed in small droplets, outgrowth of microorganisms will be limited and die-off may occur during storage. When the droplets are too coarse or when water channels are present, the aqueous phase composition, ie, the pH and salt-in-water concentration, becomes more important for the keeping quality.[39] This was recognized many years ago and microscopical methods were developed to characterize the water dispersion in butter.[58,64] Different processing regimes may result in different microstructures. Electron-microscopical examinations demonstrate that in properly worked butter, the aqueous phase is almost exclusively present as isolated, globular or elongated droplets with diameters up to about 30 μm, covered with high-melting butter fat crystals.[10,62] Water channels are usually not present in properly worked butter.

29.2.2 Initial Microflora

The initial microflora of a product is determined by the microbiological quality of its raw materials, ie, its ingredients and packing materials. The primary ingredient for butter is cream, and the initial microflora of butter is therefore to a large extent derived from the cream.

Cream

In the modern dairy situation, milk is collected on farms in refrigerated bulk tanks and transported to the dairy factory, where the fat in the milk is concentrated to obtain cream with 38% to 42% fat.[33] The cream may also be separated at the farm, which often results in cream of a lower microbiological quality, as it may be held for a week under poor hygienic conditions and not always under refrigeration.[9] Under these conditions, souring may occur spontaneously, eg, by growth of *Lactococcus lactis*, and undesirable microorganisms will start to grow. Growth of yeasts and molds, eg, *Geotrichum candidum*, may be abundant.[24] This situation is likely to occur nowadays only in areas with less advanced dairy industries.

Raw cream should be processed immediately to prevent deterioration. During storage of nonpasteurized milk or cream, psychrotrophic Gram-negative bacteria such as *Pseudomonas* spp. and *Flavobacterium* spp. may grow, leading to proteolytic and lipolytic changes and to off-flavors.[12,24,40] Off-flavors or microbial exolipases present in the cream may be carried over to the finished product and affect its quality. Vegetative pathogens such as *Listeria monocytogenes*, *Escherichia coli* O157, *Campylobacter*, and *Salmonella* spp. may be present in the milk. To kill all the relevant microorganisms, the milk and/or the cream is normally pasteurized before butter manufacture (see also Section 29.2.3). Suggested microbiological criteria for cream are aerobic plate count of <1000 cfu ml^{-1} and yeast, mold, and coliform count of <1 cfu ml^{-1}.[59] *Bacillus cereus* should be monitored regularly in view of increasing occurrence in milk of *B. cereus*,[27] spores of which survive pasteurization of milk and cream and can germinate and grow, although very slowly, at low temperatures. *B. cereus* may be relevant for sweet, unsalted, or low-salted products with coarse water droplets.

Other Ingredients

Cream may be fermented by the use of starter cultures consisting of lactococci and/or leuconostocs (cultured, soured, or ripened cream). Starter cultures can be a source of contamination and care should be taken to keep them free of contaminants. Water must always be of potable quality and drawn from a reliable source. When water is used in butter manufacture after pasteurization, eg, for washing, the water should be of a very good, potable quality. Other ingredients such as salt, the coloring agent beta-carotene, and neutralizers such as sodium carbonate are generally free of microbial contamination because of the way they are manufactured. The chemicals should be of food-grade quality.

Packing Materials

The packing material should be of a good microbiological quality. Of specific importance is the level of contamination with molds (spores), which should be as low as possible because their presence can result in mold spoilage at the surface of butter when free moisture is available at the surface.

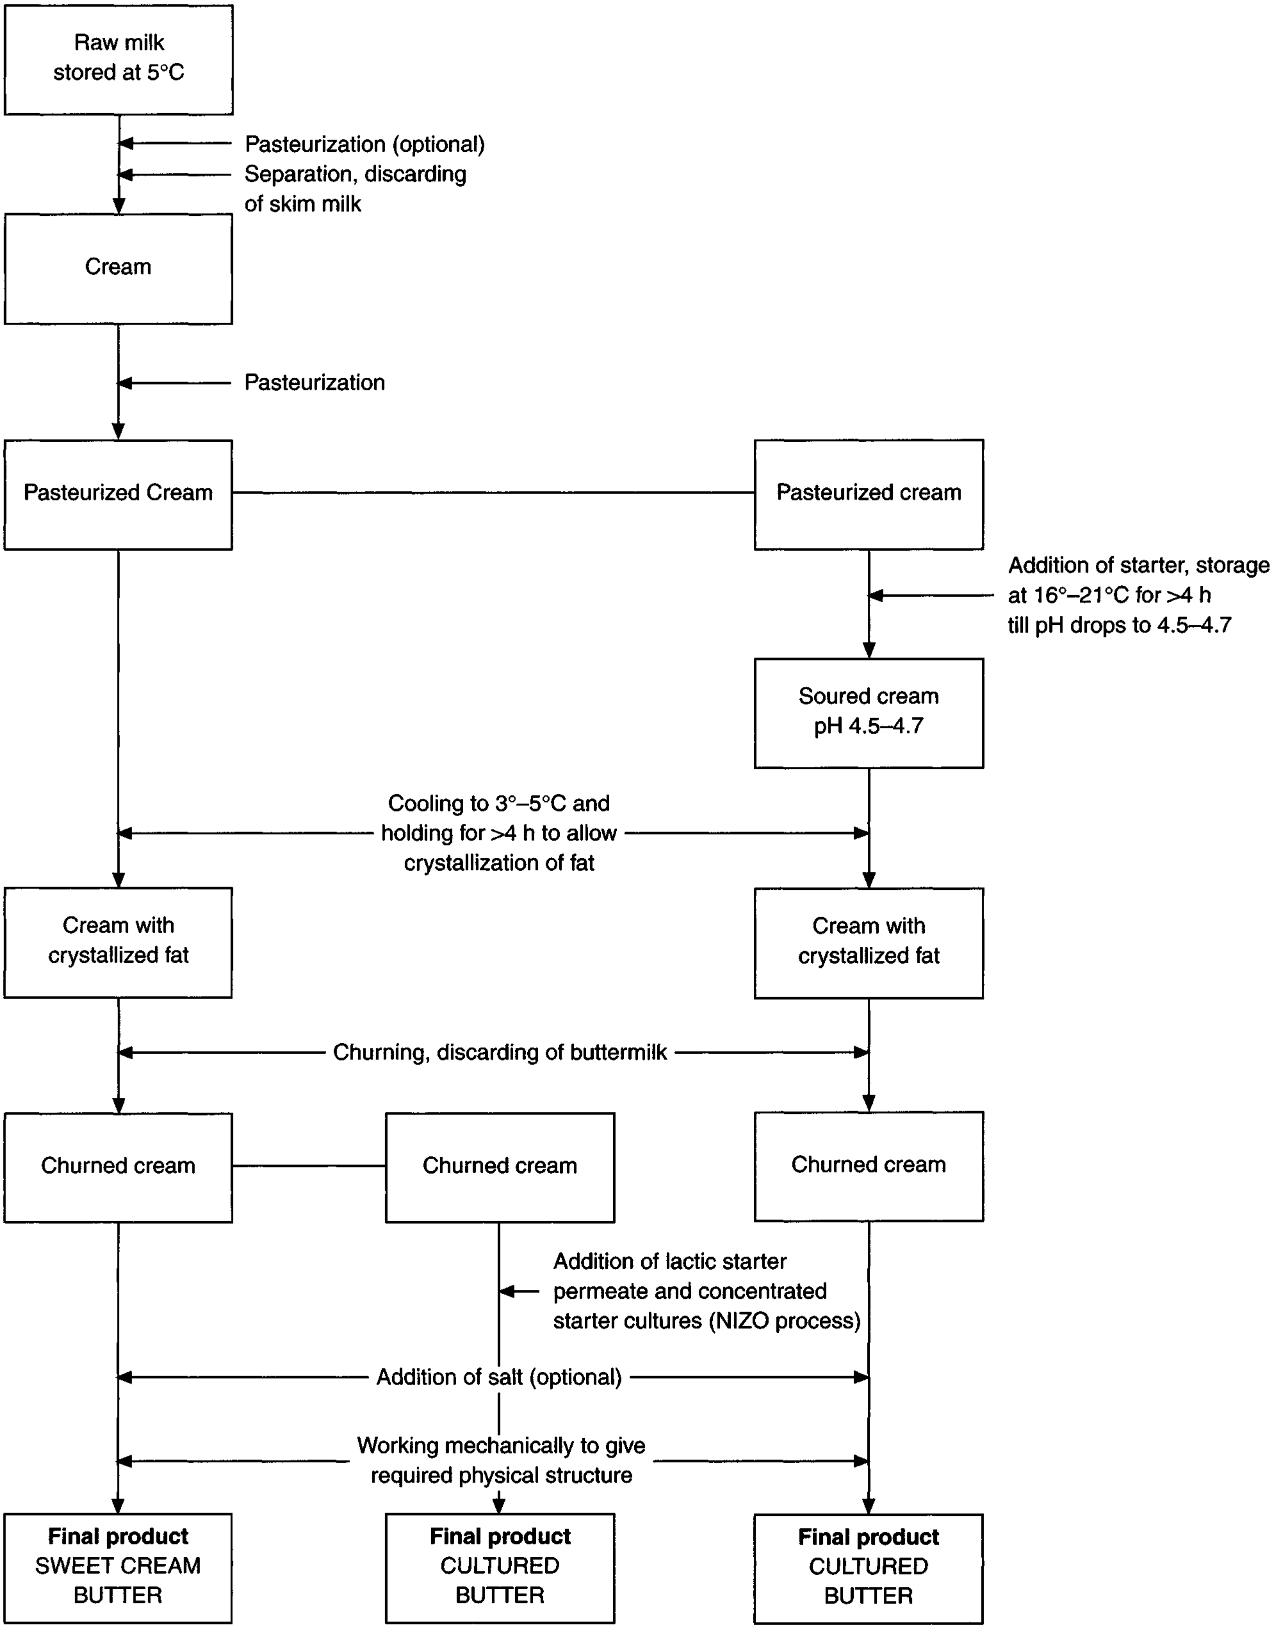
29.2.3 Processing and Its Effects on the Microflora

The butter process (Figure 29-1) starts with sweet or soured (cultured) pasteurized cream.[33] Biological fermentation of the cream produces a pleasantly aromatic flavor in the butter. In the past, cream was mostly prepared on the dairy farms where butter was also prepared. Today, the manufacturing of cream is usually separate from that of butter. The butter process can be divided roughly into two stages: (1) a churning stage in which the fat in the cream is concentrated to about 80% after which buttermilk is drained off, and (2) a working stage, in which the concentrated cream is worked into butter. In between, ingredients such as salt, colors, and concentrated starter cultures may be added. The manufacturing of cream and butter are described in more detail in the next sections.

Cream Manufacture

The milk, after reception at the factory, is usually chilled and held at about 5°C before it is separated at 46° to 49°C to yield cream with a fat content of 38% to 42%.[33,59] In some plants, the milk is pasteurized first and then cooled to separation temperature. In others, the milk is heated to separation temperature, and the cream is pasteurized subsequently. It is usual to pasteurize the cream after separation, even when the original milk is pasteurized.[59] Heat treatments (plate heat exchanger) involve temperatures in the range of 85° to 112°C,[33] but 85° to 95°C for 10 to 30 seconds is most common.[78] Batch pasteurization at longer holding times is now obsolete or confined to low technology plants in some areas of the world.[9]

If the cream is not to be soured, it is cooled quickly to 3° to 5°C after pasteurization and held at this



Raw milk stored at 5°C
Pasteurization (optional)
Separation, discarding of skim milk
Cream
Pasteurization
Pasteurized Cream
Pasteurized cream
Addition of starter, storage at 16°–21°C for >4 h till pH drops to 4.5–4.7
Soured cream pH 4.5–4.7
Cooling to 3°–5°C and holding for >4 h to allow crystallization of fat
Cream with crystallized fat
Cream with crystallized fat
Churning, discarding of buttermilk
Churned cream
Churned cream
Churned cream
Addition of lactic starter permeate and concentrated starter cultures (NIZO process)
Addition of salt (optional)
Working mechanically to give required physical structure
Final product SWEET CREAM BUTTER
Final product CULTURED BUTTER
Final product CULTURED BUTTER

Figure 29-1 Diagram of the Butter Production Process

temperature for at least 4 hours for ageing (crystallization of the fat phase). When it is to be soured, the cream is cooled to 16° to 21°C, fermented with a starter culture containing acid producers (*Lactococcus lactis* subsp. *lactis* and/or *cremoris*), and diacetyl producers (*Leuconostoc mesenteroides* subsp. *cremoris* and/or *dextranicum* and *Lactococcus lactis* subsp. *lactis* biovar. *diacetylactis*) for 4 to 6 hours (or longer) until the pH drops to 4.5 to 4.7, and further cooled down to churning temperature.[33,59] The soured butter will be particularly sensitive to oxidation if the product is salted to levels higher than 0.5%, because of the combined effect of low pH and the catalytic action of the salt.[59] In some countries, soured cream is neutralized to pH 6.0 by the addition of alkaline salts such as calcium oxide, sodium carbonate, or sodium hydroxide (continuous process).

Pasteurization of the cream is designed to destroy relevant vegetative microorganisms such as *Pseudomonas* spp. and *Flavobacterium* spp. and pathogens, such as *Listeria monocytogenes*, *E. coli* O157, *Campylobacter* spp., and *Salmonella* spp. Bacterial spore-formers and, depending on the temperature applied, some of the more heat-resistant vegetative spoilage flora, such as streptococci and *Microbacterium lacticum*, will not be killed.[28] Another important objective of the heat treatment is to improve the keeping quality by the destruction of enzymes, in particular lipases inherent in the raw cream or of microbial origin, reduction of the intensity of any undesirable flavors, and, at temperatures >105°C, production of anti-oxidant sulphydryl groups. The migration of the pro-oxidant copper from the serum into the fat phase may, however, have an opposite effect. Finally, pasteurization will completely liquify the fat for subsequent control of crystallization.[33,78]

Growth of microorganisms in the milk or cream should always be kept to a minimum by controlling time and temperature of storage. When high numbers of microorganisms are present as a result of abundant growth before pasteurization, not all relevant microorganisms may be inactivated by the usual pasteurization conditions. Bacterial spores are not inactivated by pasteurization and can germinate and grow when milk or cream of neutral pH is not sufficiently cooled. Pasteurization is a critical control point, because there are no further decontamination treatments in butter manufacture. Any failure in pasteurization could lead to the survival of pathogens. Subsequent process steps should be designed such that multiplication of those microorganisms surviving pasteurization is prevented and recontamination is minimized.

Butter Manufacture

In all major butter-producing countries, butter manufacture is nowadays a continuous process.[9,33,34,59,78] The technology is quite advanced and cleanable-in-place, stainless steel equipment is common.[35] The process starts with churning of the cream. By intensive agitation at 5° to 7°C the fat globules in the cream are converted to fat granules. The granules are then separated from the other constituents of the cream, leaving buttermilk. This results in a two-fold concentration of the fat in the cream. During churning most microorganisms are retained in the buttermilk. Cream for butter making may be washed after churning, if it is obtained from poor-quality milk, to remove off-flavors; however, this may result in recontamination of the butter with microorganisms, eg, *Pseudomonas* spp. With improved methods of manufacture and hygiene, it is now usually considered unnecessary to wash the butter granules after churning, thereby eliminating this potential source of contamination. Butter made without washing is also considered to be of better flavor.[78] In continuous butter manufacture, washing is normally not possible.

If salt is added, this is done after the last point from which buttermilk drainage can occur, to prevent entry of salt into the buttermilk. A concentration of 2% salt in the product will result in a concentration of 11% in the aqueous phase if the water content is 16% [salt/(salt + water)]. As a result, the salt-in-water concentration is theoretically increased to a range that inhibits many microorganisms. However, the salt is not always uniformly distributed over the compartmentalized aqueous phase. The butter reaching the salting stage will contain up to 14% water, which means that in order to obtain 2% of salt in the product and maintain the legal limit of 16% water content, the salt must be added as a 50/50 salt-in-water slurry. Consequently, the salt may not always be uniformly distributed over the product. This explains the occurrence of microbial deterioration even in highly salted butter.

Cultured butter has traditionally been made from cream soured by starter cultures. The sour buttermilk resulting from this process has little market value, in contrast to sweet buttermilk. For this reason increasing use is being made of the so-called NIZO process, which starts with sweet cream and yields sweet buttermilk. The NIZO process was developed by the Netherlands Institute for Dairy Research (NIZO). In this process, after churning, a lactic starter permeate that contains a high concentration of lactic acid and one or two aromatic starter cultures rich in diacetyl is worked directly into the butter to reduce the pH to <5.3 and to add flavor to the butter.[33,79] The lactic starter permeate is prepared by souring pasteurized whey with a reduced lactose content, or a similar substrate containing only milk components, by a lactic acid bacterium, eg, *Lactobacillus helveticus*, which is able to produce considerable lactic acid even below a pH of 4.5. Then the culture is submitted to ultrafiltration to remove proteins and bacteria, and the permeate is concentrated by evaporation to contain 11% to 12% lactic acid (pH 3.0). Well-known aromatic starter cultures are the culture of starter 4/25 containing *L. lactis* subsp. *lactis* biovar. *diacetylactis* as a strongly aromatic bacterium and starter Fr19 containing *Leuconostoc mesenteroides* subsp. *cremoris* in skim milk (pH 4.7).[79] The lactic starter permeate and starter culture 4/25 are mixed and aerated before being worked into the butter. The second starter culture, Fr19, is added separately. Recently, it was demonstrated that the starter culture of 4/25 can be substituted by a distillate of that culture, leaving only one starter to be cultured.[80] Because of the good taste and keeping quality of the butter, the NIZO process is widely accepted.[33] The use of a permeate or distillate of a starter culture may further add to the microbial quality of butter, as fermentation is a vulnerable step.

After churning, the butter is worked mechanically to obtain the right physical structure. A major process aim is to obtain small water droplets. Both underworking and overworking produce a final butter with coarse water droplet size distributions or even free moisture. Water droplets should preferably not exceed 10 µm in diameter. As droplet size distributions are skewed with a tail of larger droplets, this means that approximately 50% of the total water volume should be in droplets with diameters smaller than about 3 µm (volume-weighted geometric mean diameter, $\bar{D}_{3,3}$ in µm), while at the same time less than 5% of the water volume will be in droplets with diameters >10 µm.

Butter may be packed in bulk, usually up to 25-kg units, or in consumer-size portions of 10 to 500 g. Traditionally, parchment was used as the primary packing material and is still widely used, especially for larger units, but other materials have become available.[34] Larger units may, in addition to wrappers of parchment, be packed in vinyl bags. Consumer-size products are often packed in wrappers of aluminum foil laminated on the inside with parchment by means of wax, in wrappers of polyethylene, or in plastic tubs. A major disadvantage of parchment as primary packing material is, from a microbiological point of view, that cellulolytic molds are able to grow on wet parchment. To prevent mold growth, the parchment is sometimes soaked in concentrated brine plus 0.5% sorbic acid,[59,78] but this is not allowed in many countries. In general, however, to prevent mold spoilage the butter must have a fine water distribution and a surface without free moisture, and mold contamination by the environment or the packing material should be avoided.

Hygiene of Production

Butter is a rather vulnerable product and therefore strict hygienic measures should be applied. Most modern production lines are closed after pasteurization, thereby excluding contamination from the environment after pasteurization. Hygienic equipment and adequate maintenance procedures are essential to prevent contamination.[33] It is furthermore of utmost importance that the equipment is properly cleaned and disinfected before start-up of the process. The product is exposed to the environment during packaging, at which stage contamination may occur. The air in the packing environment should be of a very good quality, as butter is vulnerable to mold growth. Cardboard secondary packing material may be an important source of mold spores, especially if recycled cardboard is being used. To prevent contamination, the cardboard packing material should not be handled in the packing environment, but in a separate room. Free moisture will trigger the growth of mold spores. Moisture may condense on the surface of the product if it is moved from a cool area to an area of high humidity at the time when it is being wrapped and labeled. It is important, therefore, to control the humidity in the environment. Butter packed in bulk may be repacked in smaller packs later on. Repacking may result in enlargement of the water droplets in the butter, making the product less stable from a microbiological point of view. Butter that is repacked should be fresh or of extremely good microbiological quality, because repacking can cause the spread of microorganisms throughout the production batch. Frozen butter must be thawed in a dry and well-ventilated room to prevent moisture condensation on the butter.

Closed Shelf Life and Consumer Use

Bulk-packed butter may be stored for long periods at very low temperatures, eg, for 6 months at –15°C or a year at –30°C, which prevents growth of microorganisms. Butter should always be stored at chill temperatures (≤10°C). The storage time is then generally limited to 6 to 12 weeks. Cool and dry storage and transport is necessary to prevent mold spoilage. There is an increased risk of mold growth during cooling, freezing, and thawing when moisture can accumulate between the primary packing material and the butter surface. Because of the continuous fat phase of butter, growth of microorganisms will be localized, as is explained in Section 29.5. In addition, depending on the composition of the aqueous phase many microorganisms will not grow under refrigerated conditions. If butter is whipped or spiced, precautions should be taken to ensure that pathogens are not introduced during this process.

29.2.4 Spoilage Associations and Problems Due to Pathogens

Spoilage Associations

Butter manufacture is a fairly sensitive process from a microbiological point of view and, therefore, microbial spoilage attained considerable attention in the past.[24,28,68] With improved methods of production and hygiene, microbial spoilage of butter, produced in a modern dairy operation, is uncommon. Defects of nonmicrobial origin, such as oxidation of fat at the surface and rancidity resulting from fat hydrolysis, are probably the most frequent defects of butter nowadays. Nevertheless, microbial spoilage still occurs occasionally. Typical butter defects of microbial origin are described below.

Growth of *Alteromonas putrefaciens* (previously called *P. putrefaciens*) may lead to surface taint.[84] The surface taint defect has also been attributed to *Flavobacterium* species,[24,40] eg, to *Flavobacterium maloloris.*[24] The defect initially involves the surface layers of butter but the characteristic odor and taste may develop quickly throughout the product. It involves decomposition of the protein portion of the product and is manifested by a putrid, decomposed, or cheesy flavor, apparently from isovaleric acid or a closely related compound.[15] *Pseudomonas fragi* and *Pseudomonas fluorescens* are associated with the formation of fruity odor, caused mostly by ester formation. Because both species are lipolytic as well as proteolytic, they are also responsible for rancid odors.[24] Growth of *Pseudomonas nigrifaciens* may cause a black discoloration.[24] A variant of *L. lactis* (formerly *S. lactis* var. *maltigenes*) may cause the so-called malty-flavor defect related to the formation of 3-methylbutanal.[37] If the organism grows extensively in the cream before pasteurization, the flavor can carry over to the pasteurized cream.

Molds are still important spoilage microorganisms of butter and can result in surface discoloration and off-flavor. A variety of genera have been implicated such as *Penicillium*,[45,78] *Oospora*,[45] *Mucor*,[45] *Geotrichum*,[78] *Aspergillus*,[78] and *Cladosporium*.[45,78] Yeasts are potentially important spoilage microorganisms. Some species are lipolytic and can grow in the presence of high concentrations of salt, at low pH, and at low temperatures; *Rhodotorula* spp., *Saccharomycopsis lipolytica*, *Cryptococcus laurentii*, and *Candida diffluens* were reported as predominant yeasts in retail samples of butter.[21] Yeasts that have been implicated in spoilage include *Candida lipolytica*, *Torulopsis*, *Cryptococcus*, and *Rhodotorula*.[78]

Rancid flavor comes mainly from free butyric acid that arises from the hydrolysis of butter fat. This reaction may be catalyzed by naturally occurring lipase in the milk or by enzymes secreted by microorganisms. Milk lipase is destroyed by pasteurization.[14] Most, but not necessarily all, lipases of microbial origin will be fully inactivated by pasteurization. Microbial lipases can be rather heat resistant and their inactivation may depend on the pasteurization conditions applied. The potential carry-over of residual enzyme activity, bacterial toxins, and off-flavor to the pasteurized cream are major reasons to strictly limit microbial growth before pasteurization, even though the previously mentioned microorganisms will all be destroyed by proper pasteurization.

Problems Due to Pathogens

There are a few cases known of foodborne illness caused by butter. The reported cases concern butter and whipped butter (three cases) contaminated with *Staphylococcus aureus*,[3,74,75] blended margarine and butter products contaminated with *S. intermedius*,[43,77] green butter (made by adding parsley to butter) contaminated with *Citrobacter freundii*,[69] garlic butter contaminated with *Campylobacter jejuni*,[6] and butter contaminated with *Listeria monocytogenes*.[50] Another recall of butter, probably unsalted or lightly salted, contaminated with *L. monocytogenes* was also reported, but not related to foodborne illness.[5] The reported cases will be discussed in more detail below.

In 1970, butter was recalled by a butter manufacturer in the US in a multistate area, because the butter contained excessive numbers of bacteria and there were suspicions of a staphylococcal contamination.[3] Illness had been reported by consumers after consumption of the product. In the same year, food poisoning by consumption of whipped butter contaminated by *S. aureus* at a restaurant was also reported.[74] The contamination was traced to the butter used to prepare the whipped butter. *S. aureus* could not be detected in the milk that was added to the butter to prepare the whipped butter. The same brand of butter was implicated as the cause of a single case of typical staphylococcal food poisoning in the same year. This butter was shown to contain staphylococcal enterotoxin A.[74] In 1977, whipped butter produced by a a single manufacturing plant in the US was implicated in a multistate outbreak of presumed staphyloccocal food poisoning, which involved over 100 people.[75] Up to 10^7 *S. aureus* g^{-1} were isolated from lots of the whipped butter involved. Whipping of butter increases the risk of *S. aureus* growth, because water or milk may be added to the butter before whipping. Therefore, the product should be subjected to strict hygiene, refrigerated storage (≤7°C), and a restricted shelf life. The toxin of *S. aureus* is very heat stable and once formed as a result of poor sanitary conditions in the prepasteurization stage, might be carried over to the pasteurized product.[45]

Food poisoning by *S. intermedius* in 1991, caused by consumption of contaminated, blended margarine and butter products, involved more than 265 people in the US.[4,43,77] A single strain was identified as the causative agent, which suggests a common source of contamination rather than post-process contamination of the food products (see also Section 29.3.4). A German outbreak of infection with *C. freundii*, probably in 1994, which resulted in severe gastroenteritis and haemolytic uraemic syndrome (HUS) at a nursery school and adjacent kindergarten, was caused by consumption of green butter contaminated with verocytotoxinogenic *C. freundii*.[69] Green butter was used to prepare sandwiches and was made with contaminated parsley from an organic garden in which pig manure was used as fertilizer. Genetically identical verocytotoxinogenic *C. freundii* was isolated from most patients and from the parsley of the organic garden. Unfortunately, the green butter itself was no longer available for examination. In view of the rapid onset of disease and the severity, *C. freundii* had probably multiplied in the butter before consumption. In addition, genetically heterogeneous, verocytotoxinogenic *Escherichia coli* O157 was isolated from some of the patients and from the parsley. The genetic heterogeneity of the *E. coli* isolates together with their scarcity suggested a marginal involvement of *E. coli* in the outbreak. An outbreak in 1995 of *Campylobacter* enteritis involved about 30 people who had eaten at a restaurant in Louisiana.[6] *C. jejuni* was isolated from the patients, and epidemiological studies revealed that the illness was associated with garlic butter prepared by the restaurant.

Infectious pathogens such as *Salmonella* and *L. monocytogenes* may occur in raw milk. These microorganisms will not survive proper pasteurization, therefore butter made from pasteurized milk/cream should not contain these organisms unless post-pasteurization contamination occurs. If *L. monocytogenes* is present in butter it can survive for months when frozen (–18°C).[60] There have been a few published reports on investigation of the presence of *L. monocytogenes*[5,29,50,53,54] and *Salmonella*[11] in butter in recent years and these bacteria were not detected in the samples studied, except for a recent incident of serious contamination with *L. monocytogenes* in Finland.[50] A recall was reported in 1994 in the US of unsalted and lightly salted butter contaminated with *L. monocytogenes*,[5,63] but no cases of food poisoning were linked to this contamination. In a case-control study of a cluster of perinatal listeriosis in California carried out over a period of 6 months in 1987–1988, butter was identified as a possible vehicle for infection,[13] but no direct evidence was available. However, in 1999 a serious outbreak of food poisoning implicating butter contaminated with *L. monocytogenes* was reported in Finland.[50] Eighteen people developed listeriosis between December 1998 and February 1999, four of whom died. The mean age of patients was 57 years (range 18 to 85); all had serious underlying illnesses and were undergoing treatment in several hospitals. Most of the disease-causing strains (14/18) were of a rare serotype, 3a. *Listeria monocytogenes* serotype 3 was isolated from several places in the production facility of a Finnish dairy plant, including environmental and butter samples from the dairy plant and butter samples from the cold store of the dairy; isolates were also obtained from the kitchen of a hospital. *Listeria monocytogenes* was detected in most of the 7 g and 10 g packages of butter tested, at levels of <100 cfu g^{-1}, and once at a level of 11,400 cfu g^{-1}. The isolates from butter and epidemic isolates were indistinguishable by pulsed-field gel electrophoresis (PFGE). This PFGE-type had not been isolated previously from any other foods in Finland. The Department of Infectious Disease Epidemiology of the National Public Health Institute subsequently conducted an epidemiological investigation to strengthen the evidence of an association between consumption of butter and illness.[50]

29.3 MARGARINE

29.3.1 Composition and Structure

Composition

The composition of a margarine is, in general, strictly regulated. The definition of a margarine in the US is: "Margarine (or oleomargarine) is the food in plastic form or liquid emulsion containing no less than 80 percent fat."[76] In Western Europe, yellow fat products other than butter and melanges are described as: "Products in the form of a solid malleable emulsion, principally of the water-in-oil type, derived from solid and/or liquid vegetable and/or animal fats suitable for human consumption, with a milk fat content of not more than 3% of the fat content." The category margarines is described as: "The product obtained from vegetable and/or animal fats with a fat content of not less than 80% but less than 90%."[17]

A wide range of oils and fats may be used, eg, soya oil, palm oil, and sunflower oil. In addition to the fat blend, water (16% to 18%) and emulsifiers are required. Other ingredients include salt (sodium chloride), milk or milk products (sweet or cultured skim milk powder, buttermilk powder, sweet or acidified whey powder, milk protein), acidulants such as citric and lactic acid, preservatives, vitamins A and D, flavors, and colors such as beta-carotene. The concentration of salt may vary from 0% to 2% (w/w) or up to 2.5% (w/w) in the finished product (calculated 0% to 11% w/w on aqueous phase). In some countries, such as the UK, high salt levels are preferred. For dietary reasons, salt may be omitted. Milk or milk products are generally added as a powder in concentrations of 0.1% to 1.0% of the product. Citric and lactic acid, separate or in combination, are often used to adjust the pH. Antimicrobial preservatives that may be added in the US include sorbic acid (maximum 0.1% of the product) and benzoic acid (maximum 0.1%), or a combination thereof (maximum in total 0.2%). In Western Europe, only sorbic acid or its salts is allowed at a maximum concentration of 0.1% of the product (acid concentration).[18] The pH of the aqueous phase of a margarine is usually between 3.5 and 6.0.

Structure

Margarine contains a continuous fat phase with a network of fat crystals, which gives the consistency to the product. Most of the water is normally present as finely dispersed droplets with a diameter of <10 μm, with 50% of the total water volume in droplets smaller than about 3 μm (volume weighted geometric mean diameter, $\bar{D}_{3.3}$ in μm). A small amount, less than 5%, will be in droplets with diameters >10 μm. The droplets are covered by a shell of fat crystals, which prevents the droplets from merging together.[41] Emulsifiers, which are present at the oil/water interface, play an important role in the stability of the structure. The water dispersion introduces an effective microbiological preservation principle: a contaminating microorganism present in a droplet would be restricted in its growth either by space limitations or by exhaustion of the nutrients available in the droplet. This is a feature that margarines have in common with butter, although the latter product may have a coarser emulsion. The importance of fine emulsions for the microbiological stability of margarines is well-known,[25,72] and models have been developed that quantitatively predict the contribution of the emulsion to the microbiological stability of the product.[81–83]

The emulsion characteristics, volume weighted geometric mean diameter ($\bar{D}_{3.3}$ in μm) and geometric standard deviation (e^{σ}),[1,2] of the droplet size distribution can be determined using pulsed-field-gradient nuclear magnetic resonance (NMR).[16,55,61] In the example mentioned above, the $\bar{D}_{3.3}$ is 3.0 μm and the e^{σ} is 2.0. Alternatively, droplet sizes can be determined by microscopical techniques. The contribution of the fine water droplets to the preservation of yellow fat spreads will be discussed in more detail in Section 29.5.

29.3.2 Initial Microflora

The microbiological quality of ingredients should be ensured by purchasing on the basis of microbiological specifications. The quality of a raw material, as obtained from the supplier, can be a Critical Control Point (CCP) in a hazard analysis critical control point (HACCP) plan, if the raw material is at risk of being contaminated with relevant microorganisms and the raw material does not undergo a decontamination step when used in the production of a margarine. In this section, the microbiological issues related to the quality of the raw materials commonly used in margarines will be discussed.

Oil and Oil-Soluble Ingredients

Oil will be virtually sterile because of the high temperatures used during refining. The absence of water in the oil and the transport and processing equipment is a prerequisite to prevent microbiological problems. As water is heavier than oil, water condensate will accumulate at the bottom of tanks or in low, insufficiently flushed parts of process equipment, creating unexpected problems with molds and other microorganisms. This happens only if the oil system is improperly designed. Ingredients added to the oil, eg, flavors, colors, vitamins, and emulsifiers, generally have a very good microbiological quality and will not contribute significantly to the initial microflora of the product. Lecithin, made from soybean oil, can be contaminated with lipolytic microorganisms such as *micrococci* and, occasionally, yeasts.

Dairy and Dairy-Based Ingredients

As the milk from which these ingredients are made is always pasteurized, microbiological criteria can be quite tight, for powders, eg, aerobic plate count of <10,000 cfu g^{-1}, Enterobacteriaceae (as indicator for hygiene) <100 cfu g^{-1}, yeasts and molds <100 cfu g^{-1}, *Bacillus cereus* <1,000 cfu g^{-1}, and absence of infectious pathogens. For liquids, microbiological criteria are an aerobic plate count of <1,000 cfu g^{-1}, *Enterobacteriaceae* (as indicator for hygiene) <10 cfu g^{-1}, thermophilic bacteria <100 cfu g^{-1}, yeasts and molds <100 cfu g^{-1}, *B. cereus* <100 cfu g^{-1}, and absence of infectious pathogens. Buttermilk powder may contain high counts of thermophilic spore-formers, which is important if the stock solution of dairy ingredients or aqueous phase is stored at a temperature allowing growth. *Bacillus cereus* counts should be regularly monitored, in view of the increasing occurrence of *B. cereus* in milk.[27] The number of *B. cereus* may limit the storage time of the stock solution or the aqueous phase as its spores can germinate and grow at a minimum temperature of 4°C. The time and temperature of storage should not allow growth of spore-formers. Because the presence of bacterial spores in the finished product cannot be prevented, the composition and the physical structure of the finished product should limit their outgrowth. Some dairy-based ingredients, notably butter and butter oil, may contain harmless *Microbacterium* spp. and lactic acid bacteria. They both appear as pinpoint colonies on aerobic plate count agar.

Remaining Ingredients

Spices and herbs may be added to a margarine for flavoring purposes; there is a risk that these may be contaminated with pathogens such as *Salmonella* spp. in dry spices and herbs; *L. monocytogenes*, *E. coli* O157, and *Salmonella* spp. in fresh or frozen spices and herbs; and high numbers of spoilage microorganisms including molds and yeasts. Spices and herbs should be decontaminated by the supplier, or prior to processing by the margarine manufacturer, especially if there is no decontamination step after they have been added. Other ingredients such as salt, preservatives, and acidulants are generally free of microbial contamination because of the way they are manufactured. Water must always be of potable quality and drawn from a reliable source.

Packing Materials

The microbiological quality of the packing material is very important for margarines, as the product is cold-filled. The packing material, ie, wrappers, tubs, lids, coverleaves, and bottles, can be contaminated with a variety of microorganisms, the level of which depends on the circumstances under which the packing material is manufactured, stored, and handled. Molds are particularly relevant for margarines, as they are able to grow on the surface of the product if enough moisture and nutrients are available. The contamination level of mold spores on packing material can vary from very clean batches, ie, batches that are almost free from contamination, to batches that are contaminated with up to 5 cfu 100 cm^{-2} of packing material. Clean batches can only be manufactured when specific hygienic measures have been implemented at the source. The inside of the packing material should not be touched by hand because contamination of the packing material will result, with up to 2 to 5 cfu per touch. However, because even specific measures cannot guarantee a contamination-free manufacture of packing materials and the packing materials for margarines are never decontaminated, there is always a risk of mold contamination.

29.3.3 Processing and Its Effects on the Microflora

Overview of Margarine Process

The process is designed to prepare a mixture of (all) ingredients and to convert the mixture into a stable product consisting of an aqueous phase dispersed within a continuous fat phase. The mixture of ingredients is generally prepared via one of two routes, ie, the dual route (Figure 29-2A) or the premix route (Figure 29-2B). In the dual route, the aqueous phase and fat phase are prepared separately and combined at a later stage. The aqueous phase is prepared by adding all water-soluble ingredients, including salt and, if relevant, powdered or liquid dairy material and preservatives to potable water and adjusting the pH, if necessary, to 3.5 to 6.0 using citric or lactic acid. The ingredients may already be dis-

solved and stored separately as stock solutions. The aqueous phase is stored at 10° to 20°C, depending on the microbiological stability of the composition. The fat phase is prepared by adding oil-soluble emulsifiers, flavors, colors, and, occasionally, preservatives to the fat blend which is stored at 45° to 60°C. To create the pre-emulsion (dual route), the aqueous phase and fat phase are dosed using a proportioning pump (Figure 29-2A). The premix route is slightly different, as stock solutions of ingredients are prepared separately. A premix (or pre-emulsion) is then made by combining the ingredients in a tank using a weighing system (load cells) (Figure 29-2B). From here on the two margarine processes are the same. The pre-emulsion or premix is pumped by a high-pressure pump through a closed system of scraped

surface heat exchangers, which cool the product to 10° to 20°C and disperse the aqueous phase to obtain a fine emulsion, after which the fat phase is allowed to crystallize to a certain extent in a crystallizer (pin-stirrer). Hard margarines are packed in wrappers, soft spreadable products in tubs.

Pasteurization is optional. The composition of the aqueous phase will determine whether pasteurization is required. In the dual route, pasteurization may be required at the stage of the stock solutions, the aqueous phase, and/or the pre-emulsion, dependent on the composition of the solutions, the microbial load, the time and temperature of storage, the hygiene of production, and the microbiological stability of the finished product. In the case of margarines, in contrast to low-fat spreads, pasteurization of the aqueous phase is more common than pasteurization of the pre-emulsion. Pasteurization of both the aqueous phase and the pre-emulsion is never done. In the premix route, pasteurization can be applied at the stage of the stock solutions and/or the pre-emulsion. The design of the process should be such that during production pathogenic microorganisms cannot multiply at all and spoilage microorganisms cannot multiply to unacceptable levels.

Any hold-up at the packaging stage will create product that has to be reworked. After secondary packing, the final product is distributed and stored during closed shelf life at ambient or chilled temperature depending on several factors, such as the composition and contamination level (mold spores), factors that are also relevant to the conditions for consumer use. A HACCP study should identify the CCPs and control measures in the process. Preferably, likely CCPs should be identified at the design stage of the product and process (see Chapter 58). Three important aspects of production will be discussed here, ie, pasteurization requirements, hygiene of production, and shelf life.

Pasteurization Requirements

A 6 log reduction of relevant pathogenic and spoilage microorganisms is often defined as the aim of the heat treatment, but other criteria are also used. Whether pasteurization is required depends on the type of ingredients used and their microbial load. For some mixtures, eg, a stock solution of dairy ingredients (a so-called sensitive solution), the minimum pasteurization requirement applied for milk, 15 seconds at 72°C,[32] is sufficient. Generally, more stringent heat treatments are applied, which depend on the target microorganisms and the composition of the mixture. Target organisms can include pathogens such as *L. monocytogenes*, *E. coli* O157, *Salmonella* spp., and *Staphylococcus aureus*, and spoilage microorganisms such as yeasts, vegetative bacteria (eg, Enterobacteriaceae), and molds (mycelium and spores). Bacterial spores will, of course, survive pasteurization. Margarines based on an aqueous phase of only water and salt may not require a pasteurization step. High salt levels (≥8% on aqueous phase, ie, ≥1.4% on product, if the product contains 16% water) may significantly influence the heat resistance of relevant microorganisms.[85] Oils and fats can protect against heat treatment.[8,26,47] For margarines, such a protective effect could present a hazard when relevant microorganisms have to be inactivated at the pre-emulsion (or premix) stage. A protective effect by oils and fats is, however, only found in the absence of water or in the presence of very low levels. Because of the large amount of water present in margarines (15% to 20% on product), it is not expected that there will be a protective effect of oils and fats on the survival of vegetative microorganisms. This has been confirmed by heat-inactivation experiments with relevant pathogenic and spoilage microorganisms, performed in a model oil-in-water emulsion with a similar composition to that of margarines.[85]

Hygiene of Production

The manufacturing of margarines does not always require the same strict hygienic measures. The measures needed depend on the microbiological stability of the intermediate and finished product. Once the multiplication of relevant microorganisms can be predicted at the expected storage and/or distribution temperatures, it is possible to specify the hygienic requirements for the process and the pasteurization requirements to ensure that microbiological limits for such products will not be exceeded during the intended shelf life. This is explained in more detail in Section 29.5. If the process equipment is not sufficiently hygienic and the risk of microbiological problems is thereby too high, corrective measures are necessary. These may include product reformulation.

The preparation of the aqueous phase and the stock solutions are microbiologically vulnerable steps. There may be contamination from the environment and human sources. When temperatures over 40°C are used for extended periods, there is a risk of possible growth of thermophilic microorganisms. Sensitive raw materials, ie, ingredients such as dairy materials and proteins that may harbor spoilage and pathogenic microorganisms, must always be heat treated at some stage in the process. It is common in the margarine process to pasteurize these sensitive ingredients. Occasionally the aqueous phase or the complete emulsion (pre-emulsion or premix) is pasteurized, but the latter approach is more commonly used for the manufacture of low-fat and very low-fat spreads, which are generally more vulnerable to microbial contamination. Of course, it is of utmost importance to prevent recontamination of the pasteurized (intermediate) product as there is generally no further heat treatment in the process.

From the formation of the pre-emulsion onward, the process line will usually be closed, excluding contamination from the factory environment. The equipment can be a source of contamination, eg, of yeasts or spoilage bacteria belonging to the group of Enterobacteriaceae, if improperly designed (eg, dead spaces) or maintained (see Chapter 59). The hygienic state of the equipment is an important factor in determining the time of a production run until the next cleaning cycle.[19] It is often possible, however, to produce more vulnerable products with equipment that does not meet the highest hygienic standards, provided that the line is properly cleaned and disinfected before start-up of production. The time of a production run may then also need to be restricted. A critical step in margarine manufacturing is often the packing of the product. The design of the packing machines may be complex and often they are not cleanable-in-place. Manual cleaning is, however, difficult to control and should be avoided whenever possible. During packing the product is exposed to the environment, thus air quality is important in order to limit contamination of the product with mold spores. If necessary, a laminar air flow cabinet should be used, but this is exceptional in case of margarines. Secondary packing materials may be a source of mold spores, especially if recycled cardboard is used[65] and should preferably not be handled in the packing area. The procedures of storage, transport, and handling of packing materials should reflect the fact that these materials will contain a cold-filled food product. The packing material should not be touched by hand, as this will result in contamination, eg, with mold spores, and thereby increase the risk of mold spoilage.

If the packing machine is mechanically out-of-order or if the product has not been packed correctly, rework of the product may be required. Unpacked product can be reworked through a closed return pipeline and the product can re-enter the main line without a decontamination step, provided that the hygiene is controlled. Otherwise repasteurization is required. Packed product is reworked in a different way; the product is melted and the oil is subsequently purified in the refinery.

Closed Shelf Life and Consumer Use

The temperature of closed shelf life may be ambient or refrigerated, depending on the sensitivity of the product, the contamination level (mold spores), the type of packing material, and/or climatic conditions. From a microbiological point of view, a limitation of the shelf life period is usually not required but the shelf life is generally limited to 3 to 6 months for reasons of chemical stability. Open shelf life conditions are generally similar to closed shelf life conditions. In most cases, it is advisable to store opened packs and tubs in the refrigerator. Contamination of the product during consumer use is likely to occur but growth of contaminating microorganism is expected to be limited in view of the fat-continuous nature of the product, the small size of the water droplets, and, when applied, the low storage temperature. Upon damage of the emulsion, the product can be locally water continuous. Even then there will probably be no problems as the amount of water available may still be limited, there is not necessarily a microbial contamination at that location, and that the contamination, if present, is possibly scraped off again during further usage. In practice, preserved and nonpreserved margarines appear to be very stable products during closed and open shelf life.

29.3.4 Spoilage Associations and Problems Due to Pathogens

Spoilage Associations

Lipolytic yeasts and bacteria such as micrococci and Pseudomonaceae (*Pseudomonas, Flavobacterium*) may grow in coarse or in unstable emulsions. For this reason, in the past many products were tested routinely for lipolytic microorganisms using the Eijkman-plate.[70] Currently, testing for lipolytic microorganisms is less relevant, because major improvements in the hygiene of production and the quality of raw materials have resulted in much better quality products. Lipolytic microorganisms, especially yeasts, occasionally still cause spoilage problems, generally as a result of insufficient hygienic precautions, and can hydrolyze the fat to yield free fatty acids and trigger fatty acid oxidation.

Most spoilage problems in margarines are now caused by molds. In most cases, spoilage is evident as visible mold growth on the product but sometimes it is invisible and the cause of off-flavors or the presence of small water droplets. Mold spoilage of margarines is confined to low-salt varieties, ie, products with a salt level of <8% on aqueous phase (<1.4% on product in the presence of 16% water). Products in which the aqueous phase lacks nutrients because of the absence of a dairy ingredient, or which are preserved with sorbic acid, for example, and have a sufficiently low pH are less likely to be spoiled. Molds in margarine are detected on media such as oxytetracycline glucose yeast extract agar, with the exception of *Cladosporium* spp., which may be difficult to culture.[71,73] If margarines are contaminated with molds, these are mostly spores present at the surface of the product at a level of 1 to 5 spores per tub or package. One spore can cause spoilage of a product. Conditions that favor mold growth include higher temperatures (>10°C) and development of free moisture on the surface of the product. Differences between product temperature and air temperature can induce condensation of water. These conditions are likely to occur during closed and open shelf life and may be due to repeated movement of product in and out the refrigerator. Water can also become available for molds when the emulsion of the product is damaged by a knife, for example. Many mold species can cause spoilage, eg, *Trichoderma* species such as *T. viride*[30] and *T. harzianum*,[85] *Penicillium* species such as *P. roqueforti*[30,85] and *P. expansum*,[30] *Alternaria* species,[30,85] *Paecilomyces variotii*,[85] and *Cladosporium* species such as *C. herbarum*.[30,85] Some molds, eg, *Penicillium* species, can metabolize sorbic acid into *trans* 1,3-pentadiene in a decarboxylation step.[20] Recently, *Paecilomyces variotii* was isolated from a pentadiene-containing margarine and was demonstrated to convert sorbic acid into pentadiene,[66] which leads to an off-flavor described as a "plastic paint" and "kerosene-like"[31] or garlic-like. Because of the strong smell of pentadiene, which is detectable before mold growth is visible, it is very unlikely that the presence of this compound will not be detected by the consumer. Degradation of benzoate to benzaldehyde may also occur, but is less frequently observed.

Occasionally, spoilage may also be caused by Enterobacteriaceae, such as *Enterobacter* spp., generally as a result of a post-pasteurization contamination. These organisms generally do not cause spoilage because growth, if it can occur, is restricted by the continuous fat phase. Enterobacteriaceae, together with yeasts, serve in practice as good indicator microorganisms for the hygiene of a production line.

Problems Due to Pathogens

There are hardly any reported cases of foodborne illness caused by consumption of margarine. A US Food and Drug Administration (FDA) enforcement report mentions a recall due to contamination with staphylococcal enterotoxin from (blended) margarine and butter products.[77] The food poisoning outbreak involved more than 265 cases of illness in two states in southwestern US. In a study of 15 outbreak isolates from patients and food sources, a single, enterotoxin A–producing strain of *Staphylococcus intermedius* was identified as the etiologic agent. *Staphylococcus intermedius* was isolated from a margarine, a vegetable margarine, and different samples of butter blend.[43]

In the UK, the death of an elderly woman from listeriosis was claimed to have been caused by contamination of a margarine with *L. monocytogenes*, and margarine of the same batch was recalled from the market. However, *L. monocytogenes* was not detected in samples of the suspected margarine or of other samples from the same batch, and inspection of the factory did not reveal a risk of contamination of the product from the plant. Furthermore, there was no evidence that the *Listeria* was transmitted by the margarine.[7]

29.4 DAIRY AND NONDAIRY SPREADS

29.4.1 Composition and Structure

Composition

The fat content of water-in-oil dairy spreads and nondairy spreads can vary from 20% to 80%. Below 20% fat, spreads are in general oil-in-water. Common terms used to describe these spreads are "reduced-fat" spread, for products with a fat content of > 41% and < 62%, and "low-fat" or "light" spread, for products with a fat content of ≥10% and ≤41%.[17] Spreads made exclusively from milk fat are named dairy spreads,[17,22] those made from vegetable and animal fats, with a milk fat content of 10% to 80% of the total fat content, are called "blends."[17] Other spreads are called "fat spreads"[17,23] or "nondairy spreads," if they contain ≤3% milk fat of the total fat content.

With a decrease in fat content, the composition of the aqueous phase has become more important for obtaining a spread with a proper physical structure and an acceptable microbiological stability. The first low-fat spreads were based only on water and salt in the aqueous phase, because dairy protein destabilizes the emulsion. These products are microbiologically stable because of the very limited amount of nutrients in the aqueous phase. However, they are often not very tasteful due to the absence of a dairy ingredient (especially the absence of a dairy protein). These products are still on the market, but in addition there is now available a range of spreads containing milk or milk products, based on butter and blended spreads. Thickeners, preservative, acidulants such as citric and lactic acid, vitamins A and D, flavors, and colors may be added. Spreads containing 30% to 50% fat generally require a thickener for reasons of physical stability, with gelatin (1% to 3% of the product) often being the first choice. Spreads with a fat content of 20% to 30% may contain up to 10% carbohydrates, such as starch, alginates, and gums to structure the aqueous phase.

The microbiological stability of the spreads is usually enhanced by adding preservatives; those generally allowed are sorbic acid[18] and benzoic acid or their salts in concentrations of, for example, 0.1% (in spreads with a fat content ≥ 60%) and 0.2% (in spreads with a fat content < 60%). Because undissociated sorbic acid is the major antimicrobial agent, the pH should be sufficiently low, ie, < 5.3 and preferably < 5.0, to ensure the presence of sufficient undissociated acid. A pH of < 4.5 is generally not possible because of precipitation of dairy proteins. The salt level in the aqueous phase is generally lower than in margarine or butter, except for spreads containing 70% to 80% fat. The salt level of the product ranges in general from 0% to 1% and rarely contributes to the microbiological stability of the spread.

The composition of a reduced-fat spread may be 60% fat + emulsifier, 38% water, 1% milk powder, 0.1% citric acid, 0.5% sodium chloride, 0.06% potassium sorbate, and pH 4.9. The composition of a low-fat spread may be 40% fat + emulsifier, 55%

Next Page

water, 1% milk or whey powder, 0.1% citric acid, 0.3% sodium chloride, 3% gelatin, 0.12% to 0.16% potassium sorbate, and pH 4.9. The composition of a very low-fat spread may be 20% fat + emulsifier, 71% water, 0.1% citric acid, 0.3% sodium chloride, 8% starch, 0.16% potassium sorbate, and pH 4.9. The composition of a water-continuous very low-fat spread may be 85.9% water, 2% dairy cream (38% fat), 0.1% citric acid, 3% gelatin, 9% starch, 0.16% potassium sorbate, and pH 4.9. To these spreads, vitamins A and D, flavors, and colors are usually added.

Structure

The structure of fat-continuous dairy and nondairy spreads is in principle similar to that of butter and margarine, respectively, except that the aqueous phase may be structured by thickeners and the water dispersion is often coarser. A low-fat spread with dairy protein is more difficult to produce than an 80% fat spread with dairy protein and will generally, but not necessarily, have larger water droplets.[42,52] Continuing improvements in the control of processing conditions make the production of a 40%, protein-containing spread with a reasonable water droplet size distribution, eg, with 50% of the water volume in droplets with diameters < 15 µm and less than 5% in droplets with diameters > 90 µm, possible ($\bar{D}_{3.3} = 15$ µm, $e^{\sigma} = 3.0$). Low-fat spreads with 40% fat and lacking protein are easier to produce and often have a finer water dispersion, eg, with 50% of the water volume in droplets with diameters < 10 µm and less than 5% in droplets with diameters > 45 µm ($\bar{D}_{3.3} = 10$ µm, $e^{\sigma} = 2.5$). Spreads containing 20% fat are now generally fat continuous, but often have a very coarse water dispersion, eg, with 50% of the water volume in droplets with diameters < 50 µm and less than 5% in droplets with diameters > 300 µm ($\bar{D}_{3.3} = 50$ µm, $e^{\sigma} = 3.0$). Besides the water dispersion, the stability of the emulsion plays an important role in the microbiological stability. For example, at the surface of the product where free moisture can become available as a result of coalescence of droplets, microorganisms such as molds can grow. Water-continuous spreads with 3% to 5% fat have a gel-like, spreadable structure, which is often obtained by the use of thickeners such as starch and gelatin.

29.4.2 Initial Microflora

Most ingredients are similar to those used in the manufacturing of butter and margarine (Sections 29.2.2 and 29.3.2), except for thickeners. In general, gelatin is of a very good microbiological quality, because of the way it is manufactured, but may contain thermophilic spore-formers (in low numbers), which can grow rapidly at 50° to 55°C in a stock solution of gelatin in water. The storage time of the gelatin stock solution should not allow outgrowth of thermophilic spore-formers. In addition, the stock solution can be preserved with a low amount of potassium sorbate. Starches are generally also of a good microbiological quality but may contain high numbers of bacterial spore-formers, including *Bacillus*, particularly *B. cereus* in rice starch. Microbiological specifications for starches and gums could be aerobic plate count <10,000 cfu g^{-1}, Enterobacteriaceae <100 cfu g^{-1}, yeasts and molds <500 cfu g^{-1}, *B. cereus* <1,000 cfu g^{-1}, and absence of infectious pathogens. Generally, it is possible to obtain starches with an aerobic plate count <100 cfu g^{-1} or even lower, but this may be dependent on the type of ingredient and the region in the world from which the ingredient is bought. Because the presence of bacterial spores in the finished product cannot be prevented, the composition and the physical structure of the finished product should not allow their outgrowth.

29.4.3 Processing and Its Effects on the Microflora

Processing

As the manufacturing of most dairy and nondairy spreads is not fundamentally different from the manufacturing of butter and margarine, including the water-continuous spreads, the information provided in Sections 29.2.3 and 29.3.3 is also applicable here. There are a few differences. First, dairy and nondairy spreads are in general microbiologically more vulnerable than 80% fat spreads and may require additional measures to produce a safe and wholesome product. Furthermore, in contrast to margarines, the aqueous phase of the pre-emulsion or premix containing < 60% to 70% fat will be present as a continuous phase through part of the process. The aqueous phase will then generally be more vulnerable to growth of microorganisms. Phase inversion, ie, conversion of the water-continuous pre-emulsion into a fat-continuous emulsion, generally occurs at the emulsification step. The aqueous phase of water-continuous spreads is water continuous throughout the whole process. The type of process is similar to the premix route (Figure 29-2B). At the emulsification step, using scraped surface heat exchangers, the premix is converted into a spreadable product.

The microbiological stability of the spread will determine the hygienic requirements of the production process.[44] For vulnerable products, eg, the 40%

fat spread described in Section 29.4.1, in-line pasteurization of the complete emulsion is applied. The pasteurization aims at a 6 log reduction of relevant microorganisms. For elimination of vegetative pathogens, a process of 2 minutes at 70°C or an equivalent heat treatment may be applied. Growth of microorganisms before pasteurization should be prevented because high numbers of microorganisms may not always be inactivated by the pasteurization and, in addition, products resulting from their metabolism might remain in the form of toxins, enzymes, and off-flavor compounds, affecting the stability and safety of the product. It is advisable to decontaminate any potentially suspect raw material before the preparation of the aqueous phase or preemulsion. Interim and finished product should be tested regularly to verify that microbial growth (including that of thermophiles) does not occur during processing. Equipment should be designed to prevent contamination during processing, especially after the last decontamination step, and it should be possible to properly clean and disinfect the process line, which should preferably be done in-line. Proper hygiene during packing is of major importance, because spreads with <70% fat can be very mold sensitive. Some products, such as low-fat and very low-fat spreads and especially water-continuous spreads, may be so vulnerable to mold spoilage that special measures such as a laminar flow cabinet with sterile air may be needed and decontamination of packing materials may be necessary (comparable to aseptic packing of liquid products).

Closed Shelf Life and Consumer Use

Factors determining the storage conditions of spreads are the composition of the aqueous phase, the physical structure, and stability in the case of fat-continuous spreads, the residual contamination with microorganisms after processing, and the expected contamination during consumer use. Dairy and nondairy spreads often require refrigerated storage to guarantee a safe and wholesome product, especially during consumer use. Total shelf life is generally limited to 3 to 6 months, often for reasons other than microbiological. For some products, eg, for unpreserved low-fat spreads containing a dairy ingredient or water-continuous spreads, the duration of consumer use may be limited for microbiological reasons to 2 to 3 weeks, for example. For most spreads the duration of consumer use is, however, not limited. The residual contamination after processing can be predicted, knowing the processing conditions, and thereby largely controlled. Control of contamination resulting from consumer use is more difficult, but is very important. During consumer use the product will become contaminated with a variety of microorganisms originating from the air, bread crumbs, or from other foods. Part of the contamination will, however, be scraped off the surface by subsequent use of the product, thus the contamination is highly dependent on the (frequency of) use of the product.

29.4.4 Spoilage Associations and Problems Due to Pathogens

Spoilage Associations

Most microbiogical problems are due to mold spoilage. The same type of molds are involved as in the spoilage of butter and margarine (Sections 29.2.4 and 29.3.4). Sorbic and benzoic acid greatly reduce, but do not eliminate, the risk of mold growth. As with margarines, some mold strains are able to convert sorbic acid to 1,3-pentadiene but products containing 1,3-pentadiene will probably be rejected by the consumer because of the strong, unpleasant smell. In highly vulnerable spreads mold growth may occur during distribution even if the contamination of fresh product is below the detection limit. This explains why considerable attention must be given to packing hygiene and storage conditions. To date, water-continuous spreads have not shown more spoilage problems than fat-continuous spreads.

Problems Due to Pathogens

No reports of foodborne illness caused by the consumption of dairy and nondairy spreads, including water-continuous spreads, are known. This may be due to the attention given to controlling spoilage bacteria through stricter hygiene, which reduces the likelihood of problems with pathogenic bacteria. Pasteurization of the stock solutions, the aqueous phase, or the complete emulsion is commonly used to control infectious pathogen hazards. In addition, the fat-continuous nature of most spreads, the composition of the aqueous phase, in particular the presence of a preservative, and the refrigerated and sometimes limited storage conditions offer considerable protection against growth of pathogens during shelf life.

29.5 PRESERVATION

29.5.1 Introduction

The preservation of fat- and water-continuous yellow fat spreads relies on a complex, sometimes delicate, balance of a variety of intrinsic and extrinsic factors. Intrinsic factors are the physical structure and the composition of the aqueous phase; extrinsic factors are the temperature and time of storage and the primary packing material. To investigate whether the preservation concept ensures a safe and wholesome shelf life, several studies may be carried out in the laboratory, the factory, and even the household before the product is introduced on the market. Studies in the laboratory may include inoculation studies of the aqueous phase, but also simulation studies of closed and open shelf life. To investigate the risk of mold spoilage during closed shelf life, the surface of the product can be sprayed with a very low level of mold spores, eg, <10 spores 100 cm^{-3}. After incubation at the intended temperature of closed shelf life, the product is inspected visually for mold growth. To investigate the microbiological stability during open shelf life, the surface of the product can be sprayed with vegetative bacteria. After incubation at the relevant temperature, eg, alternating at 7° and 20°C, the product is examined microbiologically to monitor the growth of the microorganisms. Results of laboratory studies can be verified with storage trials of products made in the factory and studies in the household. Microbiological examination of products used at home by the consumer is particularly relevant when a new, sensitive type of product, such as a water-continuous spread, is introduced.

29.5.2 Intrinsic Factors

In fat-continuous spreads, the water is dispersed as small water droplets in the continuous fat phase. Sometimes water channels may be present, eg, in spreads with a very low-fat content (20%), or in butter if not properly made. The compartmentalization of water is important to the microbiological stability.[83] Contaminating microorganisms will be contained in a water droplet, the size of which can be sufficiently small that multiplication of contaminating bacteria or yeasts is physically not possible. This can be important in preventing growth of aerobic spore-formers, which are always present in butter and margarines containing a dairy ingredient, because they survive pasteurization. Growth of microorganisms may also be inhibited or restricted because the supply of nutrients in a droplet may be limited. If abundant growth occurs in a large droplet, this will often be localized. A margarine in which most of the water droplets have a diameter of < 10 μm, with 50% of the total water volume in droplets smaller than about 3 μm (volume weighted geometric mean diameter, $\bar{D}_{3.3}$ = 3.0 μm and $e^{\sigma} = 2.0$, see example in Section 29.3.1) will contain 6.6×10^0 water droplets cm^{-3}. If all droplets are large enough to contain a microorganism, at a contamination level of 10^2 microorganisms cm^{-3}, a maximum of 10^2 droplets per cm^3 would contain a microorganism and multiplication would be confined to those droplets. The sizes of the water droplets can be determined by microscopical methods or by pulsed-field-gradient NMR.[16,55,61]

The physical condition at the surface of the fat-continuous products may differ considerably from that in the bulk of the product. In addition, the microorganisms may be from a different origin, eg, from the packing material or the air to which the product is exposed during packing, or result from consumer use. For these microorganisms the compartmentalization of water is also relevant, but in a different manner. Because of the fat-continuous nature, moisture at the surface will be limited to such an extent that these microorganisms cannot grow unless condensation occurs on the surface. To base the microbiological stability of a water-in-oil emulsion on the water dispersion is of course only valid if the emulsions are physically stable. Physical stability can be ensured by a proper product design, temperature and time during storage and distribution, and proper handling during the whole shelf life. Other intrinsic factors contributing to stability, either alone or in combination, are salt-on-water, pH, preservatives such as sorbic acid and benzoic acid, possibly bacteriocines and diacetyl resulting from fermentation of milk, and limited availability of nutrients; the microbiological stability of water-continuous spreads relies mostly on these factors, in addition to the storage temperature and time. In butter and margarines, the salt concentrations can be high enough to inhibit growth of most microorganisms in the aqueous phase, eg, 2% on product can result in 11% on aqueous phase. More often it is the combined effect of salt and compartmentalization of water that is effective. Salt concentrations of 8% on aqueous phase can retard or inhibit growth of molds at the surface and thereby reduce the chance of mold spoilage, even in those cases where molds can grow in the presence of 8% salt. Yeasts may grow at extreme values of salt concentration and acidity and are difficult to control by the composition of the aqueous phase alone.

The pH is rarely sufficiently low to inhibit by itself the growth of microorganisms. In margarines without a dairy ingredient, the pH can be as low as 3.5. However, even this pH is not sufficient to limit growth of yeasts and molds. Nevertheless, the pH value of the product is critical in many products, particularly when combined with preservatives such as sorbic acid and benzoic acid. Sorbic acid is most frequently used in yellow fat spreads. Undissociated sorbic acid is active against molds, yeasts, and many bacteria, eg, aerobic spore-formers. The pH should be sufficiently low to allow sufficient undissociated acid to be present (the pK_a value of sorbic acid is 4.76). The sensitivity of molds to sorbic acid has been the subject of many investigations.[20,49] The level of preservative required depends on other intrinsic factors, such as the fat percentage, the water dispersion, and aqueous phase composition (including pH), in addition to extrinsic factors such as storage temperature and time. A concentration of 0.033% undissociated sorbic acid on aqueous phase, for example, is considered to be just sufficient to control mold spoilage in a protein-containing, fat-continuous, 40% fat spread (0.12% potassium sorbate on product, pH 4.9) during closed and open shelf life, provided the product is packed in a laminar flow cabinet to prevent contamination with mold spores and the product is stored in a refrigerator ($\leq$ 7°C). Water-continuous spreads may require higher levels of undissociated sorbic acid, ie, $>$ 0.04%, to prevent mold spoilage. Higher levels of undissociated sorbic acid can be reached by increase of the sorbic acid level and/or decrease of the pH. The pH level is, however, generally not much lower than 4.9, because lower values cause precipitation of dairy proteins. Maximum sorbic acid levels are usually subject to regulations. It is important to realize that a large part of the undissociated sorbic acid is dissolved in the fat phase and is therefore not effective as an antimicrobial, as undissociated sorbic acid has an oil/water partition coefficient of 3.3. Although the pH and the concentration of undissociated sorbic acid in yellow fat spreads rarely completely inhibit the growth of bacteria, except the outgrowth of aerobic spores, they are, in combination with other factors such as the physical structure and chilled storage conditions, critical factors in the preservation of many spreads. Growth of many contaminating microorganisms, such as Enterobacteriaceae, which are important contaminants during consumer use, is thereby prevented at the same time. During fermentation of milk with lactic acid-producing cultures, antimicrobial compounds such as bacteriocins and diacetyl may be formed. These compounds influence the growth of certain microorganisms,[38] but their relative contribution to the microbiological stability of yellow fat spreads has not been described. They may play a role in enhancing the microbiological stability, especially in combination with other factors.

The limited availability of nutrients in a compartmentalized system, such as a fat-continuous spread, can contribute considerably to the microbiological stability. Not only can the limited availability determine whether a microorganism can grow, but also whether and for how long it can survive. In the latter case, maintenance energy demands of microorganisms will determine the duration of survival.[67] Predictions of the growth or survival of microorganisms are useful to define hygienic performance criteria for manufacturing of the product, eg, pasteurization conditions and hygiene of equipment, to ensure that microbiological limits will not be exceeded during the intended shelf life. It is possible to describe quantitatively the growth of microorganisms in water-in-oil emulsions. A mechanistic model, which predicts the growth and survival of microorganisms in such emulsions, has been developed.[81] The model is based on the classical Monod equation, which describes the relationship between the concentrations of (growth-limiting) nutrients and the resulting biomass, and on the water dispersion and the distribution of microorganisms over the water droplets. Incorporated into the model are the maintenance energy required by a cell to survive and the effects of growth of microorganisms in a droplet, ie, formation of inhibitory compounds, reduction in space, and decrease in nutrient concentration. Physiological information about each type of relevant microorganism is required to predict the growth factor. The total growth factor of microorganisms in an emulsion is calculated from the growth in the individual droplets. Several assumptions were made in developing the model, among others that microbial growth in a droplet always starts from one cell and that diffusion of water-soluble nutrients through the lipid barriers between the droplets does not occur. The potential of the Verrips model to predict accurately the growth factor of microorganisms in emulsions was confirmed in validation studies: the growth of microorganisms such as *Citrobacter freundii*[82] and *Listeria innocua*[67] in fat-continuous (water-in-oil) emulsions appeared to be comparable to the predictions by the model. The model is not *a priori* applicable to lipolytic microorganisms. Studies with lipolytic micrococci and yeasts in water-in-oil emulsions, however, revealed a strongly limiting effect on growth.[83] Although there is no clear explanation for these observations, two factors are likely to be involved. First, the amount of lipase formed by a few cells in a droplet is possibly too small to provide enough nutrients for growth and, second, hydrolysis of lipids by lipases is inhibited by the coating of the fat with emulsifiers and the physical structure of the fat.[83]

The Verrips model has been proven useful in practice and was incorporated into a computer program for prediction of the stability of margarines, reduced- and low-fat spreads.[44,83] The computer program consists of two parts.[44] The first part predicts whether a selected number of microorganisms, molds excluded, can grow in the aqueous phase. For those microorganisms that are predicted to grow in the aqueous phase, the Verrips model is applied in the second part to predict to what numbers the microorganisms can grow out in the water droplets of the fat-continuous emulsion. Subsequently, the program classifies the products into hazard categories, which are ranked according to the severity of the hazard.[44] The output from the computer program is used as input into the design of the production process and shelf life conditions.

29.5.3 Extrinsic Factors

The most important extrinsic factors are temperature and storage time. The temperature required during closed shelf life to ensure a good microbiological stability will be determined by the microorganisms present in (and on) the product, the effect of intrinsic factors on these microorganisms, and the influence of temperature on the physical stability. There may be a need for (additional) control of the growth of microorganisms by storage at a low temperature (≤7°C), eg, as an extra safety measure or to prevent outgrowth of mold spores that may be present at the surface of the product. In addition, refrigerated storage may often be required to maintain a proper physical structure. During consumer use, many products will require refrigeration as the product will then become contaminated with a variety of microorganisms. Whether refrigeration is critical for the microbiological stability of a product will depend on the physical structure and the composition of the aqueous phase, for example, water-continuous spreads will always require refrigerated storage. In general, the open shelf life of fat-continuous spreads does not need to be restricted in time, because the stability can be ensured sufficiently by other factors. There may however be exceptions. Whether open shelf life needs to be restricted in time will depend on the composition of the product and the volume of the package sold.

The packing material can be of considerable importance. Parchment is often used for wrappers of butter or margarines and in some cases as cover leaves in tub products. If the parchment absorbs water, cellulolytic fungi can grow. Parchment can become wet by condensation of water when the product is transferred from cold storage to a humid and warm environment and back again, but also immediately after production during post-crystallization of the fat phase. The use of parchment impregnated with potassium sorbate is believed to reduce this risk, but this has not been demonstrated. A wrapper that does not contain parchment at the inner side, for example, parchment coated with polyethylene, is probably better to control mold spoilage. Coated parchment has the additional advantage that molds at the outer side of the package cannot come into contact with the product.

29.6 CONCLUDING REMARKS

The manufacturing of yellow fat spreads has undergone major changes during the last decades. More stringent control of hygiene during manufacture had been required for the development of microbiologically stable low-fat products. Improvements in cleaning and disinfection procedures and in the control of the quality of raw materials have been necessary. This has resulted in a range of reduced- and low-fat products with, generally, an excellent microbiological quality and, equally important, an efficient means of producing high-quality butter and margarines. Preservation of many yellow fat spreads relies on a combination of factors such as the compartmentalization of the aqueous phase, stability of the emulsion, composition of the aqueous phase, and low storage temperature. The contribution of water compartmentalization to the preservation decreases when the fat content in the product decreases. Recently, water-continuous products with fat contents as low as 3% have been introduced successfully on the market. These products are developed for spreading on bread as low-calorie alternatives for higher fat spreads. Water-continuous products lack the protective effect of the fat barrier, but this can partly be compensated for by adding more preservative. However, the products are still likely to be more sensitive to microbial growth and, although they are used as if they are a fat-continuous yellow fat spread, it should be realized that their preservation relies on a partly different principle. Up to now, water-continuous spreads have not been associated with microbiological problems, probably because considerable attention is paid to the product design, starting materials, and hygiene of processing.

In the future, special attention should be paid to define those criteria that ensure a safe and wholesome shelf life. A structured approach in evaluating the microbiology of spreads will be helpful to cope with all questions regarding the processing and stability of yellow fat products. Mathematical models describing the behavior of microorganisms in foods can be helpful in evaluating the product and process design, especially at an early stage of development or when defining the HACCP plan. However, the effort to develop and implement the models in daily practice should not be underestimated, in view of the large number of microorganisms, preserving factors, and conditions involved. A thorough understanding of the microbiology of the raw materials and the influence of processing conditions, product structure, and process hygiene on these is required to identify all hazards and risks involved in the production and stability of yellow fat spreads.

30.1 INTRODUCTION

This chapter is about the microbiological safety and stability of oil-in-water emulsions and nonemulsified products with a low pH acidified with acetic acid and other organic acids. Some heat-processed sauces will also be described. The emulsified products are mayonnaise, salad dressings, and oil-containing sauces. Ketchup, vinaigrette, and vinegar-based sauces represent the nonemulsified product types. Additionally, mustard and mayonnaise-based salads are described. The survey concludes with pasteurized acid sauces, for which vinegar is not a characteristic ingredient.

Products containing vinegar have the same major spoilage organisms (acetic acid–tolerant lactobacilli, yeasts, and molds) in common due to a low pH and the presence of acetic acid, although the vinegar is sometimes replaced by lactic or citric acid. In egg-based emulsified products, contamination with infectious pathogens like *Salmonella* and *Listeria monocytogenes* is the main safety hazard. The nonemulsified products have no specific association with pathogens. However, significant microbiological hazards are known for mayonnaise-based salads.

Nearly all these products are intended for repeat use, which sets special demands for their preservation. During consumer use, they may become contaminated with spoilage organisms and even pathogens.

30.2 MAYONNAISE, DRESSINGS, AND OTHER EMULSIFIED SAUCES

30.2.1 Composition

Mayonnaise can be a very well-defined product with specific levels of oil (min. 52%), egg yolk (min. 6%), salt (min. 1%), total acid (min. 0.75%), and pH (max. 4.0) fixed in local regulations, as in Central African Standard S_2.[30] A comparison of some regulations reveals that products with 26% oil (United Kingdom [UK]) and 80% oil (Belgium) can equally be labeled as mayonnaise (Table 30-1). The trend to low-oil products in the 1980s generally has led to reduced oil levels for mayonnaise. This is reflected in current trade practice, which includes clear labeling of fat content and reference on the label to reduced-calorie mayonnaise or similar wording. The types of oil are mainly soybean, rapeseed, and sunflower oil and sometimes cottonseed and olive oil.

The 1989 Codex Alimentarius Regional European Standard for Mayonnaise defined mayonnaise as a condiment sauce obtained by emulsifying edible vegetable oil(s) in an aqueous phase consisting of vinegar, the oil-in-water emulsion being stabilized by the hen's egg yolk.[56] This Codex standard recognized the following optional ingredients: egg white, egg products, sugar, salt, condiments, herbs, spices, fruits and vegetables including fruit juice and vegetable juice, mustard, and dairy products. Acetic acid, citric acid, lactic acid, malic acid, tartaric acid, and the salts thereof were allowed as acidifying agents. Apart from stabilizers, antioxidants, colors, flavors (together with monosodium glutamate as flavor enhancer), benzoic acid and sorbic acid, and the salts thereof were allowed as preservatives. Minimum levels for oil and technically pure egg yolk are given in Table 30-1. A worldwide Codex standard is under discussion and the 1993 draft version specifies a total fat content of not less than 65%.[57]

In 1991, the Association of the Mayonnaise and Condiment Sauce Industry of the European Union (EU) adopted a total fat content of minimum 70% and a minimal egg yolk content of 5%,[35] but these values may be reconsidered.

The United States (US) standards of identity for mayonnaise demand a vegetable oil content of at least 65% together with vinegar and/or lemon juice or lime juice as the predominant acid and egg yolk–containing ingredients.[127] According to Smittle,[116] the pH may range from about 3.6 to 4.0 with acetic acid representing 0.29% to 0.5% of the total product. The aqueous phase may contain 9% to 11% salt and 7% to 10% sugar. The water activity of three brands of regular mayonnaise was measured as 0.93, mainly due to a level of 8% to 9% of salt in the aqueous phase.[32]

Low-fat mayonnaise, reduced-calorie mayonnaise, salad dressing, salad cream, and other emulsified products made with oil, emulsifier, and vinegar typically have a lower fat content than mayonnaise. The salad dressing will have a more fluid consistency to make the product pourable, while most mayonnaise is spoonable. They normally contain egg yolk although some are made with dairy-based emulsifiers. While there is legislation to specify the composition of real mayonnaise in many countries, this is less so for low-oil mayonnaise, dressings, and emulsified sauces.

For salad dressings and French dressing, the US has compositional requirements, but most other countries do not. Salad dressings are defined by the US Food and Drug Administration (FDA) as emulsified semisolid foods prepared from vegetable oils, vinegar, lemon juice and/or lime juice, egg yolk–containing ingredients, and a cooked or partially cooked starchy paste. The finished product contains not less than 30% of edible vegetable oil and has the equivalent of 4% liquid egg yolk.[127] Typically, the pH ranges from 3.2 to 3.9, acetic acid from 0.9% to 1.2% of the total product, and the aqueous phase contains 3% to 4% of salt and 20% to 30% of sugar.[116] Standards are also set for French dressing (not less than 35% oil). In trade practice, these standards are not always followed and labeling a product as French-type dressing gives some freedom for compositional innovation.

Table 30-1 Compositional Requirements for Oil and Egg Yolk in Mayonnaise

Country	*Minimum Oil (%)*	*Minimum Egg Yolk (%)*	*Status*	
Belgium	80	7.5	legal	
Denmark	80	6	semi-official	
France	50	5.6	CoP[a]	
Germany	80	6	CoP	
Great Britain	26	2.7	legal	
Ireland	75	3.5	CoP	
Italy	70	5	CoP	
Netherlands	80	6	legal	
United States	65		legal	
Codex Regional European Standard	78.5	6	advisory	1989
CIMSCEE	70	5	CoP	1991
Codex standard	65		draft	1993

[a] CoP = Code of Practice.

As may be expected, there are few compositional specifications for other emulsified sauces, which are often referred to as dressings or sauces (meat and fish sauces). They generally contain less oil than mayonnaise and salad dressings, but all are oil-in-water emulsions in which the emulsifying agent usually is egg yolk.

Because of the presence of vinegar or other weak acids in most mayonnaise, dressings, and emulsified sauces, their pH is low, which has a significant influence on the microbiological stability. In continental Europe, the pH of mayonnaise typically is between 3.0 and 4.2, with 4.5 as the highest value (the legal maximum in Denmark). A study in the UK, however, refers to pH values up to 4.6–4.8 for commercial full-fat and reduced-calorie mayonnaise made with spirit vinegar and lemon or citric acid.[82] The percentage salt or sugar is not fixed by regulations but is mostly between 1% and 12% of the aqueous phase. The level of acetic acid in the aqueous phase is typically between 0.8% and 3.0%.

Dressings contain less fat than mayonnaise and contain starch, which helps to give the required consistency, resulting in a spoonable or pourable product. Because the aqueous phase contains lower concentrations of acid and sodium chloride than in mayonnaise, dressings are more liable to microbial spoilage. Typically the acetic acid content of dressings is 0.5% to 1.5% of the aqueous phase and the pH 3.0 to 4.2. Levels of salt (1% to 4%) and sugar (1% to 30%) in the aqueous phase contribute little to microbiological stability.

The development of novel oil-free mayonnaise and dressings has led to products that are no longer emulsified. These belong to the vinegar-based sauces (Section 30.3).

30.2.2 Initial Microflora

The microbial load of mayonnaise, dressings, and emulsified sauces comes from the ingredients used to make the product together with any contamination that may originate from the processing and packaging operation.

Microorganisms Present in Oil

The oil used is normally a refined oil that is free of microbial contamination as a result of the refining process, which involves steaming at a temperature well above 100°C. The oil has a very low moisture content of <0.1% and will thus not allow microbial growth. Contamination of the oil during transport or reception at the plant may result in transfer of the contamination to the final product. Due attention to the design, cleaning, loading, and unloading of (dedicated) road tankers will prevent this.

Microorganisms Present in Egg Yolk

Liquid egg in the form of egg yolk, whole egg, or mixtures thereof is used to produce the emulsified products described here. The egg is frequently used in the form of pasteurized liquid egg yolk preserved with salt (8% to 11%) or with salt and potassium sorbate, eg, 92% egg yolk, 7% salt, and 1% sorbate.

Raw egg is liable to be contaminated with various microorganisms of which pathogens are of most concern (Chapter 24). Normally, pasteurized egg is used but raw egg yolk from freshly broken eggs was also used in mayonnaise in past decades. The safety of the product depended on the presence of sufficient acetic acid to inactivate any pathogens before the product was shipped to the consumer (Section 30.2.5).

In view of the risk of contamination of eggs with *Salmonella enteritidis* (Chapters 24 and 45), this practice is now largely abandoned and products are made with pasteurized liquid egg, which is sometimes stated on the label. Pasteurization eliminates pathogens and, in addition, lactobacilli, yeasts, and molds that could act as spoilage organisms. European Community (EC) regulations[5] require that the pasteurized egg is distributed and stored at a temperature of 4°C or less and that *Salmonella* is absent in five samples of 25 g. The Aerobic Plate Count (APC) should not be higher than 100,000 g^{-1} and the maximum number of coliforms 100 g^{-1}. Commercial pasteurized liquid egg products often have counts well below these values. The APC commonly is a few hundred to a few thousand bacteria. The same holds for coliforms, which often are absent in 0.1 g. Occasionally, pasteurized egg products contain *Salmonella* spp. or *Listeria monocytogenes* because of inadequate pasteurization or postprocess contamination.

Microorganisms Present in Vinegar

Vinegar is a further key ingredient of mayonnaise and dressings. The vinegar may be obtained by fermentation from a range of raw materials, eg, alcohol, wine, malt, cider, etc. The acetic acid content of the vinegar typically is about 8% to 11%, but lower levels occur in specialty vinegars, such as those prepared from cider or wine.

Because of the high acetic acid content of vinegar, it is not usually liable to spoilage. It may, however, be contaminated with a very acetic acid–resistant mold, *Moniliella acetoabutans*, which can multiply at 8% to 9% acetic acid.[125] Presence of this mold in vinegar is very rare. Artisanal vinegars such as apple vinegar with low acetic acid levels occasionally may carry spoilage organisms. Vinegar used in mayonnaise, dressings, and emulsified sauces is often pasteurized to eliminate enzyme activity originating from the fermentation process. This ensures the absence of the extremely acetic acid–tolerant molds and of a rare acetic acid–resistant lactobacillus, *Lactobacillus acetotolerans,* which can multiply in the presence of 9% to 11% acetic acid at pH 5.0 and in 4% to 5% acetic acid at pH 3.5.[50]

Microorganisms Present in Mustard

Mustard is a common ingredient in many compositions of mayonnaise, dressings, and emulsified sauces. Because of (typically) 1.8% to 2.5% acetic acid in its formulation, mustard does not contain any infectious pathogens, but contamination with high levels of acetic acid–tolerant lactobacilli is well known. Yeasts are normally not found because of the antimycotic activity of allylisothiocyanate present in many mustard types. This is described in more detail in Section 30.4.

Microorganisms Present in Herbs and Spices

Most emulsified sauces, dressings, and mayonnaise get additional flavor and taste from herbs and spices. These are likely to be contaminated with spoilage organisms and pathogens (Chapter 33). Of particular concern is contamination with *Salmonella,* which is known to occur in many materials, in particular peppercorns.[98] In our experience the incidence rate in raw spices and herbs is about 1%. This makes sampling and testing impractical, so often decontaminated spices and herbs or spice extracts are used.

Microorganisms Present in Dairy Ingredients

The use of dairy ingredients in emulsified products is quite common but most of these are pasteurized by the producer. Fermented products, eg, yogurt and cheese, will have a high load of lactic acid bacteria, and yeasts also may be present. Blue cheeses require special attention due the presence of high levels of acetic acid–tolerant molds and lactobacilli. Soft cheese also may be contaminated with *Listeria monocytogenes.*

Microorganisms Present in Sugar, Salt, and Preservatives

Common ingredients, which normally have a very low microbial load, are sugar, salt, and preservatives like sorbic and benzoic acid or the salts thereof. Sugar produced in small industrial operations may be contaminated with osmotolerant yeasts such as *Zygosaccharomyces rouxii* or *Z. bailii,* which are able to cause spoilage of acetic acid–containing emulsified products.

Microorganisms Present in Water

All food products should be made with potable water, which is normally free of pathogens and acetic acid–tolerant microorganisms.

Microorganisms Present in Lactic Acid, Citric Acid, and Other Acids

Acids other than acetic acid or vinegar may be used in emulsified products. Lactic acid typically consists of a 50% or 80% solution of DL-lactic acid with no significant microbial load. Citric acid commonly is used as acid or as concentrated citric juice (30°Brix) with a low pH of approximately 3.1. Spoilage is prevented by pasteurization of the concentrate (or preservation with sulfite) to eliminate spoilage yeasts and molds. Other weak (eg, malic) or strong (eg, phosphoric) acids that may be used are free of relevant contamination.

Microorganisms Present in Starch

Starch is often used in emulsified sauces, dressings, or mayonnaise to increase the consistency. The starch can be "natural," requiring cooking to 85° to 90°C to set the starch or "instant," in which case the starch does not require any cooking. The microbial load of natural starches and instant starches normally is very low with only a few species of *Bacillus* and *Clostridium* present and no pathogens.

30.2.3 Effect of Processing

The manufacture of mayonnaise can be by a batch or a continuous process. In essence, the process consists of the mixing an oil phase (oil with oil-soluble flavors or preservatives) with an egg phase (egg yolk plus salt) and a water phase (with vinegar and additional ingredients). Sometimes starch is also included to give the product the required consistency.

In a batch process, the liquid (salted) egg yolk is typically mixed in a vessel under stirring with the acid water phase. The oil is added under intensive mixing and the resultant coarse emulsion is usually passed through a colloid mill to achieve the small oil droplets (predominantly 5–10 μm) required for a good consistency. Consistency of spoonable mayonnaise is expressed in Steven's value, measured by recording the resistance in g of a measuring gauge pressed into the product at a fixed speed. Steven's values typically are between 50 and 200 g. For liquid products, the Bostwick value is used, which is the run length in cm of the product, when released in a measuring tray and measured within 30 seconds. Typical values are 5 to 10 cm. The inclusion of (cooked) starch is optional and depends largely on the oil content of the mayonnaise. The freshly made mayonnaise is pumped to a holding vessel, and packaged in glass jars, tubes, buckets, or other containers for consumer/professional use.

In a continuous process, a set of proportioning pumps combines the required amounts of liquid egg, oil, water phase, and optionally a cooked starch phase, which are coarsely emulsified in an emulsifying cylinder (with static and rotating pins) and finally passed through a colloid mill. When particulates are present in the food, the starch phase can be added (through an in-line mixer) directly to the final product buffer vessel. Further details on processing of mayonnaise and dressings were published by Lopez.[84]

In the manufacturing of a mayonnaise, there is normally no technological need to apply a heat process unless elimination of enzymes is required from ingredients like vinegar or spices. These enzymes could break down the starch, if present. The aqueous phase containing ingredients such as herbs or mustard, which could contain pathogenic or spoilage microorganisms, may be pasteurized before mixing. As noted above, egg yolk or other egg products are pasteurized by the supplier before use.

The production of many other emulsified products with a lower oil content, such as low-oil mayonnaise, salad dressing, and thousand island dressings is similar, but most contain (cooked) starch to give the required consistency. Some are simply made by introducing a starch phase into a mayonnaise base. In a dressing with particulates made in a batch process, the particulates can be mixed after the colloid mill with the dressing base. An alternative route to prevent product damage is to omit the colloid mill and to introduce the particulates in the first mixer after preparation of the dressing base.

The overall effect of the mayonnaise, dressing, and emulsified sauce manufacturing process on the initial microbial load of the ingredients used is practically nil, when no heat is applied in the process. All emulsified products described in this section have a continuous water phase and the behavior of the microbial load thereof is not affected by the presence of oil droplets. Whether the organisms present are able to survive or multiply in the product depends on the composition of the aqueous phase, in particular, the acetic acid concentration, pH, salt, and preservatives.

30.2.4 Spoilage Associations and Pathogen Hazards

With respect to spoilage, only those organisms able to survive and grow in these products, with a low pH in the presence of acetic acid or other acids, are considered relevant. Micrococci and bacilli, which have been shown to be present, are not discussed because they cannot grow in this acid environment. Bacilli, nevertheless, are reported to spoil dressings; however, reports cited[79] are over 60 years old. No recent reports are known. The authors have not observed any case of spoilage by *Bacillus* spp. in 20 years; it is their opinion that statements about this are outdated and likely to be incorrect.

Spoilage

Microbial spoilage of mayonnaise, dressings, and other emulsified sauces containing vinegar is mainly caused by a small group of acetic acid–tolerant yeasts and lactobacilli, whereas spoilage by molds is very rare because most molds have a limited tolerance of acetic acid.[117]

Yeasts. Acetic acid–resistant yeasts are a frequent cause of mayonnaise and dressing spoilage. *Zygosaccharomyces bailii* and *Pichia membranaefaciens*, can both multiply in the presence of *ca.* 3% acetic acid,[67,78,123] but the latter yeast requires the presence of oxygen and therefore spoilage only occurs at the surface of these products.[117] These strains are responsible for the majority of the spoilage incidents by yeasts. Other species sometimes implicated are *Zygosaccharomyces rouxii*, *Saccharomyces cerevisiae* and *Candida magnolia*, *Z. bisporus* and *Rhodotorula mucilaginosa*, and *Debaromyces hansenii*. Yeasts may cause spoilage by gas formation or by growing as brownish colonies, which sometimes may appear as small oil-like droplets on the surface of mayonnaise. On occasion only limited growth within the product is observed to approximately 10,000 cells g^{-1} and full development is inhibited, probably by oxygen depletion resulting from oxidation of oils and metabolic action of the yeasts.

Lactobacilli. *Lactobacillus fructivorans* is the main lactobacillus reported to cause spoilage of mayonnaise-like products.[117] In fact, in our experience *L. plantarum* and *L. buchneri* are the lactobacilli most frequently isolated from spoiled products, whereas *L. fructivorans* is more uncommon. *L. plantarum* can multiply to very high numbers without causing evident spoilage, which may result in underreporting. Growth of heterofermentative lactobacilli results in gas formation and a decrease in pH, resulting in visible spoilage.

Molds. Molds rarely present a threat to the stability of mayonnaise and dressings because the majority cannot grow in the presence of 0.5% acetic acid.[67,76] Furthermore, the amount of oxygen present is often limited because of steam capping of jars followed by consumption of oxygen by oil oxidation. Growth of a *Geotrichum* species on the surface of mayonnaise in jars that were not well-closed has been reported.[71] *Moniliella acetoabutans* is a uniquely acetic acid–tolerant mold found in acetic acid preserves; this mold can utilize acetic acid and thus tolerate levels in excess of 5%.[41] Tuynenburg Muys[125] referred to this and other acetic acid–resistant molds such as *Monascus ruber* and *Penicillium glaucum*, which can grow in the presence of 1% and more of acetic acid. *Penicillium roqueforti*, which is present in blue cheese, also belongs to this group. Spoilage by any of these molds is very rare for the reasons stated above.

Pathogens

Salmonella. Mayonnaise has been the cause of many outbreaks of salmonellosis. A major outbreak with 10,000 cases in Denmark in 1955 led to a Danish regulation that the pH of mayonnaise should be below 4.5.[71] Thereafter, there were two additional Danish incidents with *Salmonella*-contaminated mayonnaise from large kitchens. In the first, the pH of the mayonnaise was 5.1 and the count of *Salmonella* was 180,000 g^{-1} at the time of analysis 4 days after the meal.[101] The *Salmonella* was identified as *S. typhimurium*, biochemical type 17. The second outbreak involved 41 cases and 2 fatalities. The mayonnaise for a salad was made with raw egg and 2 days after the event the *Salmonella* count of the mayonnaise was 6 million g^{-1}.[87] Again *S. typhimurium*, type 17 was observed and the pH of the mayonnaise was 6.0.

In 1976 a serious salmonellosis outbreak occurred among passengers on four flights to and from Las Palmas (Spain). There were 6 fatalities, and approximately 500 passengers became ill. *Salmonella typhimurium* phage type 96 was isolated from mayonnaise used on the incriminated flights as well as from a food handler involved in the preparation of the mayonnaise.[43] The pH of the mayonnaise was not mentioned in the World Health Organization (WHO) report on the incident but the menu list referred to mayonnaise, mayonnaise acidified with tomato sauce, and "salsa rosa" (mayonnaise and tomato) suggesting the possibility that the mayonnaise with tomato sauce was not properly acidified and thus allowed growth of *Salmonella.*

These early *Salmonella* incidents were probably caused by *Salmonella* from food handlers or raw egg in combination with an elevated pH of the mayonnaise, which allowed survival and/or growth of *Salmonella*. Such events, however, were rare at that time. It was well known that the inside of duck eggs was likely to be contaminated with *Salmonella* spp. and these eggs were printed with an instruction to cook before use. For sound hen's eggs, *Salmonella* was not considered a significant hazard, although potential contamination with *Salmonella* from the outside of the shell was recognized.

A new wave of *Salmonella* food poisoning was reported in the 1980s due to contamination of hen's eggs with particular phage-types of *Salmonella enteritidis* (see Chapter 24). In Spain, homemade mayonnaise caused a very significant increase in foodborne illness due *to S. enteritidis.* The latter became responsible for 78% of all outbreaks of known etiology.[99] In the UK, homemade mayonnaise made from raw eggs became equally a common cause of infection with *S. enteritidis* (see Chapters 24 and 45).

Similarly, in the US, Argentina, and many other countries, cases of food poisoning due to *S. enteritidis* from homemade or restaurant-made mayonnaise occurred.[49,120] In a serious US outbreak, 404 of the 965 persons at risk (mean age 64.2 year) in a New York City hospital became ill and 9 people died (median age 77.5 years). The source of the incident was hospital-prepared mayonnaise made with raw eggs, and contamination with *Salmonella enteritidis* could be traced back to a farm corporation.[121]

Outbreaks of infection with other *Salmonella* spp. have been associated with the use of raw egg. In the UK, 120 people from a total of 700 reported gastrointestinal illness after eating in the House of Lords.[91] *Salmonella typhimurium* definitive type 49 was isolated from a tartar sauce, made from mayonnaise, remaining from the meal. The mayonnaise was made from fresh eggs, oil, and vinegar. The same *Salmonella* type was isolated from the patients and from hen droppings from the farm that supplied the eggs. A few further incidents caused by *S. typhimurium* are reported in the review by Radford and Board.[104] The use of raw egg for mayonnaise contributed to an outbreak at a wedding reception in 1992, in which 81 guests and 11 catering staff became ill due to *S. enteritidis*. The company and the director were prosecuted and fined.[31]

In 1995, in Uruguay 600 cases of salmonellosis were traced to sandwiches that were made with small batches of mayonnaise. The source of the contamination was *S. enteritidis* from unpasteurized eggs. The company switched to pasteurized eggs thereafter.[11]

Nearly all these incidents were caused by mayonnaise made at home, in institutional kitchens, or in restaurants. It is now well known that *S. enteritidis* can survive for a few days in mayonnaise at 20° or 30°C, when citric acid or a low level of acetic acid is used as acidulant.[77,83] In homemade mayonnaise with 0.1% of acetic acid (0.85% acetic acid in the water phase), *S. enteritidis* survived for 5 to 6 days at 30°C but only for 1 day in commercial mayonnaise with 2.26% acetic acid in the water phase. Refrigerated storage of a homemade mayonnaise at 10°C gave less than a factor three reduction in 9 days, while *Salmonella* was eliminated from the commercial mayonnaise (5 log reduction) in 3 to 6 days.[77] Similar findings were reported by Lock and Board.[82,83] An overview of the inactivation rates of *Salmonella* in mayonnaise is given by the International Commission on Microbiological Specifications for Foods (ICMSF).[72]

The use of pasteurized egg yolk, sufficient vinegar to give typically more than 1% acetic acid in the water phase, and a pH below 4.5 have prevented foodborne illness from industrially produced mayonnaise during the past 40 years. The general public is now more aware of the hazards associated with raw egg, and the use of pasteurized egg may be explicitly declared on the label. Consumer organizations no longer state that the best mayonnaise is made at home from oil, vinegar, and raw egg but they warn against homemade mayonnaise and dressings made with such eggs.[7,68] In some countries, the regulations were changed to protect the consumer, for example, in Spain, where in restaurants, bars, and central kitchens, raw eggs for preparation of mayonnaise and sauces for direct consumption are no longer permitted and where the eggs must be replaced by pasteurized egg products.[90] Additionally, this mayonnaise should be max. 8°C at the point of consumption with a final pH not over 4.2 and be kept for not longer than 24 hours.

Staphylococcus aureus. The inactivation of *Staphylococcus aureus* in mayonnaise has been well studied by Smittle.[116] Because of the low pH of these commercial products and the presence of acetic acid, the organism is unable to grow and is normally of no significance for mayonnaise and dressings. This is comparable to margarine and butter for which only one incident is known.[6] In a Danish incident, however, contamination with 1 million of δ-toxin–producing staphylococci was observed in *Salmonella*-contaminated mayonnaise with an atypical pH of 6.0.[87] Radford and Board[104] refer to two outbreaks caused by *S. aureus*, but the "Stacey's Southend" outbreak was not caused by mayonnaise but by sandwiches with chopped eggs.[4] Details of the other outbreak could not be traced.

Listeria monocytogenes. Contamination of raw egg yolk with *Listeria monocytogenes* has been observed[80] and its behavior in reduced-calorie mayonnaise was studied.[60] In products with pH 3.9 and 0.7% of acetic acid in the aqueous phase *L. monocytogenes* did not grow at 23.9°C and was inactivated by a factor of 10^4 within 3 days. In four commercial mayonnaise products with pH 3.3 to 3.9, *Listeria* inactivation at 26.6°C was directly related to aqueous-phase acetic acid concentrations; at 2.2% acetic acid the pathogen was reduced by a factor of 10^8 in 72 hours and at 0.67% acetic acid in 192 hours.[51]

***Escherichia coli* O157:H7.** Mayonnaise was epidemiologically implicated as the vehicle for transmission in a 1993 outbreak of *E. coli* O157:H7 disease with 62 illnesses in Oregon, US, because of mayonnaise-based ranch dressing, blue cheese dressing, and seafood salad. The victims were mostly adult truckers; only four children were involved.[8,9] The evidence available suggested that the mayonnaise (pH 3.9) was contaminated by tainted meat at the retailer. The bulk mayonnaise as delivered was not suspect.[10] This incident stimulated research on *E. coli* O157:H7 in mayonnaise, but no *E. coli* O157:H7 contamination of pasteurized egg yolk or of the wet processing environment in three processing plants for mayonnaise or other emulsified sauces was discovered by Erickson et al.[53] The primary source for this enterohemorrhagic *E. coli* (EHEC) appears to be cattle. Meat and milk from cattle have been directly linked to many outbreaks, but the Oregon outbreak has shown that recontamination of mayonnaise and dressings with this pathogen may lead to unexpected outbreaks, which thus created interest in the survival of this pathogen in an acid environment. There is another report of a possible outbreak due to mayonnaise contaminated with a nonmotile *E. coli* O101, where 300 people became ill in Eastern Germany in 1988.[29]

E. coli O157:H7 has been shown to be rather resistant to acid pH as suggested by an outbreak associated with consumption of apple cider[21] and by survival in apple cider inoculated with *E. coli* O157:H7,[136] although similar survival is known for *Salmonella*.[65] *E. coli* O157:H7 survived much better than a control strain of *E. coli* at low pH and numbers remained unchanged after 24 hours of incubation in trypticase soy broth at pH 3 and 4.[89] In commercial regular mayonnaise and reduced-calorie mayonnaise dressing, *E. coli* O157:H7 survived 7 days at 23.9°C and survived better than the strains of *Salmonella* and *Listeria monocytogenes* tested.[61]

In studies by the US FDA the following observations were made on the survival of three strains of *E. coli* O157:H7 in the mayonnaise implicated in the Oregon outbreak.[129] When an inoculum of 10^8 cells g^{-1} was mixed with the mayonnaise, pH 3.65, the EHEC strains died off rapidly and survived for max. 72 hours at 25°C, but at 7°C the strains could be recovered up to 35 days. Survival of one EHEC strain at 5°C in four sauces made from this mayonnaise was about 35 days in thousand island dressing (pH 3.76); for seafood sauce (pH 4.38) and blue cheese dressing (pH 4.44), the numbers of surviving EHEC were about 500 times higher at that point in time. In a fourth, mayonnaise-mustard sauce, pH 3.68, the inactivation at 5°C was very rapid as no survival was observed after 5 days; this may be explained by the antimicrobial factors present in mustard (see Section 30.4).

Similar findings were reported for two strains of *E. coli* O157:H7 inoculated into a commercial mayonnaise, pH 3.91, at a level > 10^6 g^{-1} as no survival was observed after 96 hours at 22°C.[105] In a ranch salad dressing at pH 4.51 and 4°C survival was much better (more than 17 days). In this study also a strain of *E. coli* and *Enterobacter aerogenes* were used as references. These strains died more rapidly in the mayonnaise and ranch dressing than the *E. coli* O157:H7 strains, with no survival after 48 hours in mayonnaise nor after 14 days in refrigerated ranch dressing. The mayonnaise had a composition meeting the FDA requirements for pH and acetic acid in products containing raw egg.[128] These regulations were meant to ensure inactivation of *Salmonella* by holding mayonnaise for 72 hours before shipment. Recent studies[53] once more confirmed the rapid inactivation of EHEC in commercial mayonnaise with pH values below 4.0. The conclusion was that intact packages of commercial mayonnaise and mayonnaise dressings pose negligible EHEC contamination and health hazard risks.

Other Pathogens. Foodborne pathogens like *Clostridium botulinum*, *C. perfringens*, and *Bacillus cereus* cannot grow in mayonnaise and dressings at a pH below 4.6 and thus should be of no significance. Nevertheless, reference is made to an outbreak in the UK caused by *B. cereus* (and *Staphylococcus aureus*).[104] The pH of the product involved may have been above 4.6, thus allowing growth of these pathogens. *Campylobacter jejuni* has been found in egg yolk but the organism is not heat resistant, is unable to grow at ambient temperature, and is likely to be inactivated rapidly in the presence of acetic acid. One incident was reported in the Netherlands of campylobacteriosis due to a homemade mayonnaise,[3] but details of the incident were not included.

30.2.5 Preservation

The production of mayonnaise, dressings, and other emulsified sauces should be carried out in such a way that contamination with pathogens is prevented and that no spoilage of the final product occurs. A good product design therefore addresses the safety as well the stability of these products. During the product and process design phase and the implementation of the new compositions in an actual manufacturing process, the principles of the Hazard Analysis Critical Control Points (HACCP) system (Chapter 58) should be followed.

Product Safety

Because of the use of egg, the pathogens associated with emulsified products are in particular *Salmonella*, *Listeria monocytogenes*, and *Staphylococcus aureus*. Verotoxigenic *E. coli* might also be considered a pathogen of concern. Two approaches are needed to ensure product safety: (1) to adopt measures to ensure that viable infectious pathogens are not present in the product at the point of consumption and (2) to formulate the product in such a way that pathogens cannot multiply in the product, if contamination occurs.

Absence of Infectious Pathogens. For the industrial manufacture of mayonnaise, dressings, and other emulsified sauces the absence of infectious pathogens from the products can best be ensured by the use of pasteurized egg and pasteurization of all other components that may present a microbiological hazard such as some dairy ingredients or herbs and spices. Pasteurization of egg is used in nearly all industrial production and sometimes a second pasteurization of the egg is applied directly before processing to ensure product safety, as a very low incidence of *Salmonella* and *Listeria monocytogenes* may occur in commercially available pasteurized liquid egg. Such a low level of contamination cannot be detected by endpoint testing using any reasonable number of samples (Chapter 60).

Pasteurization of potentially contaminated ingredients can be done as a separate processing step for herbs and spices, for example, or this can be integrated in the manufacturing process itself. Such in-plant pasteurization is, however, not always applied for the ingredients for which a pathogen hazard may exist. An alternative is to buy all hazardous ingredients from approved suppliers, who control the pathogen hazard by a validated HACCP-based system.

A further approach may be to accept some potential contamination of ingredients and to rely on the pH and composition of the product to eliminate the pathogen hazard. This concept is best illustrated by past practice in the US. Making use of the intrinsic microbial safety of properly formulated mayonnaise and salad dressings is an approved practice in the US, where according to the federal regulations raw eggs or raw egg yolk–containing ingredients may be used, provided that the pH of the dressing is not above 4.1, and the acidity of the aqueous phase expressed as acetic acid is not less than 1.4%.[128] The final product must be held for 72 hours before it is shipped to consumers. This practice has been shown to eliminate *Salmonella* from mayonnaise, when contaminated raw eggs were used, but the use of raw eggs was discontinued commercially in the early 1970s.[60] The US regulation is based on studies on survival of *Salmonella* and *Staphylococcus aureus* in mayonnaise and salad dressings.[131] In these studies, rapid inactivation of *Salmonella* at room temperature or at 37°C within 1 to 6 hours was shown for salad dressing (pH 3.2–3.3; *ca.* 1% acetic acid) and within 1 to 18 hours for mayonnaise (pH 3.8–4.0; *ca.* 0.5% acetic acid). *Staphylococci* survived under these conditions for up to 4 days.

These findings are still relevant to (re)contamination of pasteurized egg or mayonnaise with *Salmonella*. For reduced-calorie mayonnaise, the use of 1.4% acetic acid in the aqueous phase of the mayonnaise would be organoleptically unacceptable, but the elimination of *Salmonella* occurs at 0.7% acetic acid.[60] In typical American reduced-calorie mayonnaise, *Salmonella* and *L. monocytogenes* were inactivated by 4 log in 3 days in products with a pH below 4.1 and 0.7% acetic acid in the aqueous phase. An investigation in the UK with 24 varieties of commercial mayonnaise with pH values of 2.6 to 4.8 and various types of acids showed rapid inactivation of *Salmonella enteritidis* PT 4, when this organism was inoculated into the products at a level of 2.5×10^4 g^{-1}.[82] In eight examples no *Salmonella* could be recovered after 48 hours from products stored at 20°C and *Salmonella* was undetectable after 20 minutes in a fat-free mayonnaise with pH 2.6. At 4°C, *Salmonella* survival generally was longer. In the paper the *Salmonella* inactivation is expressed as $\log_{10}$ decimal reduction times (DRTs). The $\log_{10}$ DRTs (in minutes) for products with a pH of *ca.* 3.7–4.7 were *ca.* 2–3.5 at 4°C and *ca.* 2.5–3.5 at 20°C.

A safety evaluation similar to that of Wethington and Fabian[131] was done by Tuynenburg Muys.[125] He studied survival of Enterobacteriaceae in mayonnaise and dressings after inoculation with *ca.* 5×10^4 cells ml^{-1} of *Enterobacter aerogenes* and *E. coli*. When after 3 days at 20°C the number of Enterobacteriaceae was reduced by a factor 1,000 (so-called 3D concept) the products were declared safe with respect to Enterobacteriaceae. Later, the safety analysis with respect to Enterobacteriaceae was developed into a formula in which pH, undissociated acetic acid, sugar, and salt were incorporated to predict inactivation of *Salmonella* on the basis of the aqueous-phase composition of the product.[36] Because of the widespread use of pasteurized egg and the incidence of new pathogens like *Listeria monocytogenes* and EHEC, this formula has lost most of its significance as a tool to predict safety of new formulations.

The more resistant *E. coli* O157:H7 survived for 7 days in commercial mayonnaise.[61] Inoculation of 6.5 × 10^3 *E. coli* O157:H7 in the commercial mayonnaise, pH 3.6–3.8 and 0.37% titratable acid, implicated in the 1993 Oregon outbreak (Section 30.4) showed survival for 8 to 21 days at 20°C and 34 to 55 days at 5°C.[137] Presence of *E. coli* O157:H7 in raw materials for mayonnaise and other emulsified sauces is, however, not likely, so this is not a major point to be considered during the development of a new product.[53]

Prevention of Growth of Pathogens. To prevent growth in emulsified sauces of pathogens, which might get into the product during use by professionals (catering) and consumers, it is recommended that a composition is chosen that does not permit growth of any pathogen.

Salmonella spp. can multiply down to a pH of 3.8,[72] so pH alone will be inadequate in most emulsified products to stop multiplication of this pathogen, but the content of acetic acid will also contribute to preservation. This will stop multiplication at a much higher pH. For three strains of *Salmonella* the minimum pH for growth in an optimal medium with acetic acid was 5.4, but it is not possible from the data given to deduce the level of acetic acid present.[33] In reduced-calorie mayonnaise of pH 4.3

with 32.7% oil, 0.1% potassium sorbate, and only 0.1% total acetic acid (in the aqueous phase) no growth of *Salmonella* occurred and 10^6 cells of eight *Salmonella* strains were eliminated within 1 week at 23.9°C.[60] The survival of *S. enteritidis* in homemade mayonnaise acidified with vinegar and lemon juice was studied by Perales and García.[100] In a mayonnaise of pH 5.0 containing 0.65% acetic acid in the aqueous phase (calculated from information in the paper) and thus 0.23% undissociated acetic acid, no growth of *S. enteritidis* occurred within 120 hours at 24° or 35°C. In the mayonnaise acidified with vinegar to pH 4.5, *Salmonella* survived well at 24°C, but at 35°C the numbers declined by a factor of 10^6 in 120 hours. In mayonnaise acidified to pH 5.0 or 4.5 with lemon juice, good growth of *Salmonella* was seen at both 24° and 35°C.

The possible growth of *S. aureus* and toxin production in homemade mayonnaise was recently studied in a rather unusual experimental design, where the mayonnaise was diluted with 62.5% sugar syrup (2:1). The latter must have reduced the acetic acid concentration of the vinegar in the mayonnaise by about four-fold.[62,63] Toxin was found only in mayonnaise acidified with vinegar with a pH $\geq$ 5.0. At pH 4.9 and less no growth took place and no toxin was formed. The concentration of acetic acid in the water phase of the mayonnaise in these trials could not be estimated.

For *Listeria monocytogenes*, the minimum pH for growth at 30°C of 16 strains, isolated from patients and outbreaks, in a laboratory medium acidified with HCl was 4.4–4.6.[59] It would be expected that the limiting pH for growth would be significantly higher when acetic or lactic acid was used as acidulant. In TSB, acidified with acetic acid, growth was observed at pH 5.0 for two out of four *L. monocytogenes* strains, while at pH 4.5 a level of 0.044 M (0.26%) undissociated acetic acid inhibited growth in TSB and cells were reduced by a factor 1,000 within a week at 30°C.[38] In reduced-calorie mayonnaise at pH 4.3, 0.1% of acetic acid in the aqueous phase and 0.1% potassium sorbate, *L. monocytogenes* did not grow at 23.9°C but was reduced by a factor 10^6 within 1 week.[60] In a laboratory medium at pH 4.4 to 4.6 with 0.2% acetic acid (corresponding with *ca.* 0.15% undissociated acetic acid) no growth of two strains of *L. monocytogenes* was observed at temperatures from 7° to 35°C.[2] Cells survived at this level of acid, but were inactivated with 0.3% acetic acid. For lactic acid and citric acid, the findings were very similar with 0.2% (no growth) and 0.3% (inactivation), but addition of 0.1% acetic acid was clearly more inhibitory than citric acid, with lactic acid at an intermediate position.

For *E. coli* O157:H7, the minimum pH for growth is probably above pH 4.0.[136] In All Purpose Tween broth acidified with acetic acid to pH 5.0 (but no concentration given) no growth was observed in 70 days,[44] but in brain heart infusion broth at pH 5.0 acidified with lactic acid visible growth of *E. coli* O157:H7 was evident in 2 to 3 days at 25°C. In a detailed study,[37] the growth and survival of *E. coli* O157:H7 at 4°, 10°, 25°, and 37°C in Tryptic Soy Broth with yeast extract (TSBYE) acidified with acetic, citric, lactic, malic, and mandelic acid to pH 4.0, 4.5, 5.0, 5.5, and 7.0 was determined. These studies showed growth at 37°C at pH 5.2 but not at pH 4.5, when pH was adjusted with acetic acid. When the pH was adjusted with citric or lactic acid, these pH values became pH 4.5 (growth) and 4.0 (no growth). At 10°C and pH 5.5, only pH adjustment with acetic acid prevented growth of EHEC as all other acids tested gave good growth within 21 days. The no growth–growth threshold level for acetic acid in the TSBYE medium at pH 5.2 was given as 7 mM undissociated acetic acid, which corresponds with 0.042% undissociated acetic acid. Studies in microtiter plates at 30°C with a range of inocula (10 to 10^5 cells per well) with a mixture of five *E. coli* O157:H7 strains at pH values from pH 3.8 to 5.5 and undissociated acetic acid levels from 0.0% to 0.05% gave complete inhibition of EHEC for 28 days at all inoculation levels in Trypticase Soy Broth at pH 5.1 and 0.04% undissociated acetic acid. At pH 4.6, the growth was prevented by 0.035% undissociated acid, corresponding with 0.06% total acetic acid.[76] With the same levels of undissociated lactic acid, good growth of *E. coli* O157:H7 was seen for all conditions tested.

Based on the above data and the information that EHEC is considered to be one of the more acetic acid–tolerant pathogens, the following product safety rule with respect to pathogen growth has been formulated by the authors of this chapter: "No growth of pathogens will be possible, when the emulsified products have a maximum equilibrium pH of 4.5 and at least 0.2% undissociated acetic acid in the aqueous phase." This corresponds, depending on the pH, to roughly 0.2% at pH 3.0 to 0.3% at pH 4.5 total acetic acid in the aqueous phase, which is well below the level used in most commercial products. When all the acetic acid is replaced by lactic acid or citric acid, the rule is no longer applicable as lactic acid and citric acid are much less inhibitory to *E. coli* O157:H7, *Salmonella,* and *L. monocyto-*

genes.[1,33,37,76] Additional information on the antimicrobial effects of weak organic acids is given in Chapter 8 and in the review of Smittle.[116]

Product Stability

The presence of more than 0.2% undissociated acetic acid in the aqueous phase of an emulsified sauce will control pathogen growth, but this level is not enough to prevent the growth of acetic acid–tolerant spoilage organisms. Some yeasts and lactobacilli can grow in the presence of up to 3% undissociated acetic acid. It is, however, not essential that products do not permit microbial growth. Emulsified sauces should reach the consumer with a low microbial load, and products should not spoil after opening when handled according to the instructions on the pack. This objective can be met in various ways as will be explained later.

The low pH of 3.0 to 4.5 and the preservative effect of undissociated acetic acid (mostly added as vinegar), lactic acid, or other weak acids is most important for stability. In full-fat mayonnaise, salt and to a much lesser extent sugar can reduce the water activity significantly, which may help to inhibit spoilage organisms. Because of a limited water content, the salt concentration in the aqueous phase can be as high as 12% resulting in a water activity (a_w) of about 0.92. The typical compositions of mayonnaise reported by Smittle[116] have 9% to 12% salt and 7% to 10% sugar in the aqueous phase, which will significantly affect growth of lactobacilli and to a lesser extent yeasts. For dressings, an a_w of 0.91 is reported to be inhibitory for *L. fructivorans* and a value of 0.89 for *Zygosaccharomyces bailii.*[88] The combination of pH and water activity for the yeast and lactobacillus gave inhibition of both organisms by the combination of pH (3.3 to 4.1) and a_w (0.85 to 0.89/0.93). For *L. plantarum,* the inhibiting a_w for growth in the presence of salt was 0.943 to 0.960, whereas *Saccharomyces rouxii* still could grow at an a_w <0.868.[106]

In addition to pH, salt, and acetic acid, preservatives like sorbic acid can be used where legally allowed, but a major proportion of the acid will dissolve in the oil phase. According to our calculations for dressings with pH 3.8–4.5 and fat levels of 20% to 80% on average only 30% to 60% of the sorbic acid will be present in the active undissociated form in the aqueous phase to protect against yeast (and lactobacilli). When benzoic acid is used, an even larger proportion of the preservative dissolves in the fat phase, which makes it not very effective. The permitted levels of sorbic acid and benzoic acid within the European Community[13] are summarized in Table 30-2.

Table 30-2 Preservatives Permitted in the EU in Emulsified and Nonemulsified Sauces, Salads, and Mustard

	Maximum Level (mg kg^{-1} or mg l^{-1} as appropriate)[1]			
Foodstuff	*Sorbic Acid*	*Benzoic Acid*	*Sorbic + Benzoic Acid*[2]	*Sulfite*[3]
Emulsified sauces with a fat content of 60% or more	1000	500	1000	
Emulsified sauces with a fat content less than 60%	2000	1000	2000	
Nonemulsified sauces		1000		
Prepared salads		1500		
Mustard, excluding Dijon mustard			1000	250
Dijon mustard			1000	500

[1] The maximum levels of the preservatives sorbic and benzoic acid are expressed as the free acid.

[2] This means that sorbic acid and benzoic acid may be used singly or in combination.

[3] Sulfite is expressed as SO_2.

The preservatives may be added as sorbic acid (E 200), potassium sorbate (E 202), calcium sorbate (E 203), benzoic acid (E 210), sodium benzoate (E 211), potassium benzoate (E 212), or calcium benzoate (E 213).

Sulfite may be added as sulfur dioxide (E 220), sodium sulfite (E 221), sodium hydrogen sulfite (E 222), sodium metabisulfite (E 223), potassium metabisulfite (E 224), calcium sulfite (E 226), calcium hydrogen sulfite (E 227), or potassium hydrogen sulfite (E 228).

Stability Evaluation. The stability of newly developed emulsified sauces is often not easily established and challenge studies with typical acetic acid–adapted strains of lactobacilli, yeasts, and molds were introduced by Tuynenburg Muys.[125] He demonstrated that only a limited number of spoilage organisms were suited to grow in the typical ecological niche presented by these products. An inoculation technique, which was part of the so-called Microbiological Composition Analysis, was used to test the stability and safety of products. For stability testing various strains were used of *Lactobacillus buchneri*, of yeasts (*Pichia membranaefaciens* and *Zygosaccharomyces bailii*), and of molds (*Monascus ruber* and *Penicillium glaucum*).

With a set of typical acetic acid–resistant organisms (*Moniliella acetoabutans, Saccharomyces acidifaciens [= Zygosaccharomyces bailii], Pichia membranaefaciens,* and *Lactobacillus buchneri*) data were collected by Tuynenburg Muys[125] to construct a spoilage-prediction chart for dressings. This chart was an extension of the preservation-prediction chart of Bell and Etchells[19] for the spoilage of sweet cucumbers by *Zygosaccharomyces globiformis (= Torulaspora delbrueckii)* with acetic acid and sugar as variables. The chart of Tuynenburg Muys[125] used the percentage of undissociated acetic acid in the water phase and the amount of salt and sugar (expressed as grammolecules). The prediction chart was later transformed into a formula to estimate the stability of new formulations. In these predictions *Moniliella acetoabutans*, which is extremely resistant to acetic acid, was not taken into consideration, otherwise no emulsified product could be made stable as this mold can grow at 8% to 9% undissociated acetic acid. In practice this mold is extremely rare and can be dealt with by pasteurization of natural vinegars used.

The stability formula is based on *S. acidifaciens (= Z. bailii)*, the next most acetic acid–tolerant organism in the chart. The formula with the growth-limiting concentration for acetic acid, salt, and sugar for pH values between 3.0 and 4.5 is as follows[35]:

$$\Sigma\ 15.75 \times \text{undissociated acetic acid (\%)} + 3.08 \times \text{salt (\%)} + \text{hexose (\%)} + 0.5 \times \text{disaccharide (\%)} = 63$$

In this formula all percentages are w/w, based on the weight of the solutes in the aqueous solution, ie, water plus acetic acid plus salt plus sugars. For acetic acid containing sauces with a stability factor, Σ, above 63, stability was predicted, whereas products with a value below 63 might be vulnerable for spoilage.

An additional development was the creation of a safety formula, which was derived from a number of challenge tests, as described before in the safety evaluation:

$$15.75 \times \text{undissociated acetic acid (\%)} + 3.08 \times \text{salt (\%)} + \text{hexose (\%)} + 0.5 \times \text{disaccharide (\%)} + 40\ (4.0 - \text{pH}) = \Sigma s$$

Products with values for Σs above 63 would be intrinsically safe with respect to pathogenic Enterobacteriaceae, indicating that these would die quickly (factor 1,000 reduction in 3 days at 20°C). Because of the use of pasteurized egg, this formula, which is comparable to the rules developed in the US for mayonnaise with raw egg, lost its significance and safety is better ensured by raw material selection or pasteurization.

The derivation of the stability formula was one of the first attempts to model microbial growth in a food product. In retrospect, the formula is rather fail safe. The formula would require, for example, presence of 4% undissociated acetic acid or 1% undissociated acetic acid and 15% salt in the aqueous phase to stop microbial spoilage, when no significant levels of other inhibitors would be present.

The formula has been used for some time to predict stability of new formulations and still may be applied for some products. However, the requirement for less acidic products with lower concentrations of vinegar and salt has resulted in the need for additional methods of preservation, including the addition of sorbic acid, pasteurization, and refrigeration.[35] Improved control of hygiene during production also contributes to the stability of the products.

Product Design for Emulsified Sauces. Three stability classes may be distinguished:

1. **Stable products.** These products are stable at ambient temperatures, not sensitive to spoilage, whether open or closed, because of an aqueous phase composition that inhibits growth of all relevant spoilage organisms, in particular acetic acid–tolerant lactobacilli, yeasts, and molds. Their closed shelf life will be 6 months to 1 year, limited for organoleptic reasons only. After opening, the sauces are not sensitive to spoilage and they can be kept at ambient temperatures or chilled for as long as their quality remains acceptable.
2. **Unstable products.** These products allow (slow to rapid) growth of lactobacilli and/or yeasts, but good process design and hygienic practices can eliminate or prevent contamination during

manufacturing, allowing long ambient shelf life in the closed jar (6 months to 1 year). Recontamination during consumer use restricts the shelf life of the product after opening to a few weeks (ambient) or months (chilled).

3. **Fresh, chilled products.** Because of minimal built-in preservation, these products have only a short chilled shelf life; contamination should be kept at a low level and chilled distribution is needed to give the required shelf life of a few weeks.

Water Phase Composition. To judge the microbiological stability of emulsified sauces, it is important to know the aqueous phase composition of the product. This may be measured analytically, but often the composition of the product can be calculated when the composition of all ingredients is known (% water, fat, acetic acid, salt, preservatives, etc).

For the antimicrobial effects of acetic acid and other weak acids used as preservatives, the undissociated form of the acid is important. This level can be calculated once the total amount present, the pH, and the dissociation constant, pKa, are known. It is important, however, that a large part of the undissociated acid may dissolve in the oil phase and be lost for preservation. For acetic acid this is a minor part as the partition coefficient oil/water is about 0.03 to 0.07 (average value 0.05). For sorbic acid this coefficient is 3.3, while for benzoic acid most of the undissociated acid goes to the oil phase due to a oil/water partition coefficient of 6 to 13 (average 10).[26]

In the Netherlands, Kneteman developed the formula below (not published) to calculate the true aqueous phase composition. Similar formulae were published later[85,126,133]:

$$C = \frac{C_w \times (\%\text{water} + \%\text{acid})}{100} + \frac{C_w \times \alpha \times D \times \%\text{oil}}{0.9 \times 100} \qquad (1)$$

In which:

C = total concentration of acid in the product
C_w = concentration acid w/w in aqueous phase
α = undissociated part of the acid
D = partition coefficient oil/water of the undissociated acid
0.9 = specific weight of the fat phase

α can be derived from:

$$\alpha = \frac{1}{10^{(\text{pH} - \text{pK})} + 1} \qquad (2)$$

Because the undissociated acid is the inhibitory factor, equations (1) and (2) can be combined to calculate the percentage of undissociated acetic-, sorbic-, or benzoic acid in the aqueous phase as:

undissociated acid, % w/w =

$$\alpha \times \frac{100 \times \%\text{acid}}{\%\text{water} + \%\text{acid} + \dfrac{\alpha \times D \times \%\text{oil}}{0.9}} \qquad (3)$$

As lactic acid (HLa) does not dissolve in oil the percentage of the undissociated form of this acid is calculated by using the formula below:

HLa undissociated, % w/w =

$$\alpha \times \frac{100 \times \%\text{HLa}}{\%\text{water} + \%\text{HLa}} \qquad (4)$$

For the above acids the partition coefficients oil/water and pKa values are given below based on[26]:

	D	pKa
Acetic acid	0.05	4.76
Benzoic acid	10	4.19
Lactic acid	0.0	3.86
Sorbic acid	3.3	4.76

Once the aqueous phase composition of an emulsified sauce is known, the stability can be estimated. This is best done for each of the main types of spoilage organisms (as they differ in their susceptibility against the common preservative factors).

Molds rarely will present a problem as those normally present are unable to grow because of the presence of elevated levels of undissociated acetic acid (>1.5%) or the presence of a preservative like sorbic acid. Yeasts are more difficult to inhibit as they require over 3% undissociated acetic acid in the aqueous phase or an inhibitive combination of a lower level of acetic acid and a preservative such as sorbic acid. They are not affected by a low pH.

Lactobacilli are affected by low pH, by a reduced water activity (high salt or sugar levels), and by undissociated acetic acid. Sorbic acid is less effective against lactobacilli than against yeasts, but it may contribute to stability.

The preservation potential of the weak acids found in emulsified sauces is quite variable. Citric acid generally has no specific antimicrobial activity against the typical spoilage flora of emulsified sauces and its main function is to reduce pH. Lactic acid (undissociated) has the same preservative power as acetic acid (undissociated) against lactobacilli, but its activity against yeasts is much less.[133] The effect on molds is marginal. Most studies on antimicrobial activity of weak acids were, however, done with bacterial pathogens (see Chapter 8).[116] In these studies, acetic acid proved to be more inhibitive than lactic acid, with minimal inhibition by citric acid. Similar results were recently obtained for *L. monocytogenes*[38] and *E. coli* O157:H7.[37]

Limited general guidance can be given about the best preservation for the large variety of emulsified sauces on the market as these range from perfectly stable products to rather vulnerable fresh mayonnaise.

For microbiologically stable products, a process design based on a cold process may be adequate, but an infectious pathogen hazard should be prevented by application of pasteurization for critical ingredients like liquid egg (yolk), as explained earlier.

For microbiologically unstable mayonnaise and dressings, the process design should control contamination hazards originating from ingredients and the environment. Products that are not very sensitive to spoilage may be made with clean ingredients (free from relevant spoilage organisms) under Good Manufacturing Practice conditions based on the General Principles of Food Hygiene of Codex Alimentarius.[55]

More sensitive products may require decontamination of all suspect ingredients, for example, by inclusion in a water phase, which is pasteurized. The process line itself should be free of relevant microbial contaminants at the start of the process. The use of hygienically designed process equipment and packaging machines is the key to the production of such vulnerable products. For those products, a process line that can be cleaned-in-place (CIP) is preferred. This allows the best control over cleaning and disinfection. Proper manual cleaning may still be required for traditional colloid mills, fillers, and other equipment that are difficult to clean by CIP alone because of crevices in the equipment construction, for example.

For chilled products, hygienic processing and clean (decontaminated) ingredients are important, together with proper refrigeration of the product. Equipment traditionally used for the manufacture of mayonnaise and dressings has not been easy to clean, but recently hygienic mixers, colloid mills, valves, pumps, and filling machines that can be "cleaned in place" have become available and their use is recommended. The glass jars, tubes, or other containers used for packaging mayonnaise and dressings are normally free of acetic acid–resistant spoilage organisms, and thus there is no need for decontamination or for extremely clean packaging materials.

For fresh, chilled emulsified sauces, the aqueous phase composition should be known to be able to deduce what the effect would be of chilled distribution and storage on the shelf life. When the chilled chain is of good quality it is likely that yeasts become the limiting factor for shelf life because lactobacilli growth is significantly inhibited by temperatures below 10°C.

Consumer use is a final point to consider. Many mayonnaise and dressings are only spoiled by acetic acid–resistant organisms, which are not widespread in the consumer's home. Consequently, these products will not easily spoil during consumer use. When, however, mild compositions with low acetic acid levels are put on the market, the possibility of spoilage during use should be considered. Such spoilage can be controlled largely (but not completely) by limiting the shelf life of opened product at ambient temperatures or by recommending chilled storage after opening. Label instructions are thus important for these products.

30.3 KETCHUP, VINAIGRETTE, AND OTHER NONEMULSIFIED SAUCES

30.3.1 Composition

The main nonemulsified sauces are ketchup and vinaigrette. Ketchup is made with tomatoes, sugar, salt, vinegar, water, and spices like onion, garlic, cinnamon, and cayenne, but no oil.[94] Normally at least 6% of the dry matter should come from fresh tomato or tomato paste. Sugar or corn syrup form the major part (20% to 30%) of the total solids. The high sugar and high dry matter content in ketchup results in a reduction of water activity to levels of 0.93–0.95. The amount of vinegar added typically results in 0.8% to 1.0% of acetic acid in the product. The spices may be replaced by oleoresins or extracts. Often starch is added to give the product the required consistency, however, this is not permitted in all countries. In those countries, the product with starch is often labeled as a tomato sauce. The pH of ketchup is normally between 3.5 and 4.0. Ketchup may be preserved with benzoic acid or sorbic acid to give sufficient open or closed shelf life. The closed shelf life is about a year at ambient temperature, while the open shelf life can be weeks to months at chilled temperature, depending on product composition and presence of preservatives.

Vinaigrettes are nonemulsified dressings of vinegar and oil for use on green salads. The oil is not present as a true emulsion, but gums are added to produce a temporary or semi-permanent or permanent colloid, which behaves like an emulsion. In two-phase vinaigrette the oil and water phases are separated, and consequently, the product requires shaking before use. Spices and condiments are added to give flavor to the product.

The most commonly used oils are soybean, sunflower, rapeseed, olive oil, corn, cotton, or grape oil. The vinegar may be derived from alcohol, wine, cider, malt, or many other sources. The gums commonly used are xanthan, locust bean gum, carrageenan, gum arabic, guar gum, and others. The herbs and spices used could be tarragon, chives, pepper, and chili, while onion may be added as a powder or as particulates. Mustard is often present. The pH of vinaigrettes is typically 3.0–3.5. They often have a high level of vinegar and thus acetic acid, which will contribute significantly to microbiological stability, but preservatives are sometimes also required.

Ketchup and vinaigrette are two representatives of a large spectrum of nonemulsified sauces. A further example is salsa, which like ketchup is tomato-based but the concentration of vinegar is lower and may go down to 0.1% to 0.2% acetic acid. Fat-free imitation mayonnaise is a further example of this group of products.

30.3.2 Initial Microflora

The initial flora of ketchup, vinaigrette, and other nonemulsified sauces with vinegar depends largely on the raw materials used and originates from herbs, spices, tomato, and onions. Tomato paste is preserved by heat and is free of vegetative spoilage organisms (and pathogens). The paste can be provided in cans, drums, or aseptically packed in bags, which after opening are sensitive to recontamination, and lactobacilli may develop when held after opening. The microflora of vinegar, herbs and spices, starch, and mustard is discussed in Section 30.2.2. Vegetables such as onions can carry elevated levels of lactobacilli, but sometimes also yeasts or molds.

30.3.3 Effect of Processing

Normally, ketchup is made by mixing all ingredients, which are then cooked to 85° to 90°C to set the starch, usually followed by hot filling into bottles. This eliminates contamination with spoilage organisms from raw materials or the manufacturing process itself. Because of the hot fill, contamination during the filling operation will be eliminated. In case of heat-sensitive, plastic, up-side-down bottles a cold-fill process has been applied. In the latter operation, it is particularly important to prevent recontamination of the cooked and cooled ketchup with spoilage organisms from the processing and filling equipment. Hygienic design and proper cleaning and sanitation are essential.

Most vinaigrettes are processed without pasteurization of the aqueous phase because the gums used for stabilization of the oil droplets do not require a cooking step. Raw material selection, pasteurization of components, or choice of compositions that are high in acetic acid are required to ensure the safety and stability of these products.

30.3.4 Spoilage Associations and Pathogen Hazards

Ketchup is often sensitive to spoilage by lactobacilli; Dakin and Radwell[40] refer to *L. brevis*, *L. mannitopeum*, and *L. plantarum* as spoilage organisms identified in studies of tomato ketchup. The lactobacilli are controlled by cooking and hot filling at temperatures above 70°C. In products filled at lower temperatures, lactobacilli are the predominant spoilage organisms. Lactobacilli can be present in spoiled products in the form of large white spots or as small, hard, white dots, which may easily be mistaken for undissolved ingredients or clumps of starch. The lactobacilli can grow with or without gas formation. In the former case, swelling of plastic containers will be seen. Explosion of glass bottles with ketchup is a hazard, particularly when yeasts would spoil the ketchup. Reports on spoilage by yeasts, however, are few.[39,119] The acetic acid–tolerant yeasts that may cause spoilage of ketchup are the same as those that spoil mayonnaise because these products have the same associative flora.[124] Restaurant-made taco and enchilada sauces with a pH of 4.5 to 4.7 spoiled with lactobacilli, yeasts, and molds because of high initial contamination from spices and honey and recontamination of the cooked sauce by unhygienic practices.[48] The use of ethylene oxide–decontaminated spices, pasteurized honey, proper cooking, and prompt chilling gave a chilled shelf life of 2 weeks.

Spoilage of vinaigrettes is less common because of built-in preservation factors, such as a low pH and relative high acetic acid concentration, which give good open and closed shelf life.

Because of the absence of liquid egg and dairy ingredients in ketchup and vinaigrette, there is no direct association of pathogens with these sauces. Herbs and spices may introduce pathogens such as *Salmonella*, but these will be killed by the cooking process of the ketchup or rapidly inactivated by the typically high level of acetic acid in vinaigrettes.

There have been no reports of foodborne illness resulting from these sauces.

30.3.5 Preservation

For safety, a minimum of 0.2% undissociated acetic acid and a pH below 4.6 will be adequate to prevent growth of pathogens (see Section 30.2.5). Such pathogens may originate from raw materials or may get into the sauces during consumer use. At acetic acid levels below 0.2%, growth of pathogens should be considered, although pathogen growth on occasion may be inhibited without vinegar as shown for *Salmonella*, *S. aureus*, *E. coli*, and *B. cereus*. These pathogens were inactivated within 10 days when inoculated into a tomato-based Mexican hot sauce, pH 4.1, made from water, tomato puree, canned hot chili peppers, and salt.[54] The stability of cooked sauces such as ketchup is based on a low pH, reduced water activity because of sugar and acetic acid in combination with either a hot fill or a cold, hygienic fill without recontamination. Cold-prepared vinaigrettes often have a rather low pH of 3.0 to 3.5, which inhibits many lactobacilli, and an elevated level of acetic acid of 1.0% to 2.0%, which provides a fair degree of built-in stability.

Preservatives such as sorbic acid or benzoic acid can be used to improve the closed or open shelf life in combination with refrigerated storage after opening. The above-mentioned tomato-based Mexican sauce spoiled because of yeasts. However, addition of 0.05% of either sorbic acid or benzoic acid prevented yeast growth, when incubated at 25°C for 8 hours and then at 5°C for 16 hours for a period of 10 days.[54] In this investigation no reference was made to lactobacilli but it is possible that these equally were present as the "total counts" of spoiled sauces were over 10^7 ml^{-1}. Whether the added preservatives were adequate to inhibit lactobacilli as well was not investigated.

In the EU 1,000 mg kg^{-1} of sorbic or benzoic acid is permitted for nonemulsified sauces (Table 30-2), but in our experience such levels are not adequate to give complete inhibition of lactobacilli in ketchup and additionally acetic acid or other factors may be required for effective preservation. For ketchup, benzoic acid is often more effective than sorbic acid because it is almost equally active against lactobacilli and yeasts, while sorbic acid is less so against the lactobacilli.[133] In vinaigrettes with a low pH of 3.0 to 3.5, lactobacilli may be inhibited by pH and sorbic acid may be best suited to give the required stability with respect to yeasts.

30.4 MUSTARD

30.4.1 Composition

For centuries mustard has been one of the most important spices used in many foods. The word mustard is derived from the Latin word "mustum" or "must," the juice of grape or other fruit. In the ancient Roman-occupied Britain must was mixed with powdered mustard seeds and used as a paste called "mustum ardens" (hot must).[114]

Dry mustard seed does not have a distinct aroma. The typical sharp pungent taste of mustard develops as soon as the seed is soaked in water. Mustard can be produced from different varieties of seeds. Nowadays, these seeds are mainly cultivated in Canada. Depending on the pungency of the product required the seed variety is chosen. If produced from brown (*Brassica juncea*) or black (*Brassica nigra*) mustard seed, a very hot mustard like "Moutarde Dijon," will be the result. If produced from white or yellow mustard seed (*Sinapis alba*) a much milder product, "Moutarde Douce," is obtained. Combination of the various types of seed results in intermediate products.

The concentration of seed in the different paste varieties varies from 17% to 30%. Legislation for Dijon mustard specifies that it is should be produced from *Brassica juncea* only and that the product should not contain more than 2% of the husks of the grains; furthermore, the dry matter content should be at least 28%. For other varieties, the husks are equally milled in. Besides the grains, the product contains water, salt, vinegar, spices, and, depending on the local taste, sugar or sometimes honey. Typical compositional values for mustard are as follows: acetic acid between 1.8% to 2.5%, salt content between 2.5% to 6.5%, fat content 4% to 8%, a total dry matter 18% to 28%, and a pH of 3.8–4.3.

30.4.2 Initial Microflora

The initial microflora of mustard is mainly a reflection of the microbiological contamination of the mustard seeds, water, vinegar, salt, sugar, and the spice mixtures used and the hygienic status of the equipment. Mustard seeds can be highly contaminated. In a production line of a mustard mill contamination levels of aerobic and anaerobic spore-formers were 10^2 to 6.10^4 and 10^3 to 5.10^4, respectively, and lactobacilli were at levels of 4.10^3–4.10^5.[75] The contamination level of the brown and black seeds generally is higher than of the white seeds. In a survey to determine the microbiological quality of spices and herbs,[98]

Next Page

coliforms and *B. cereus* could be found and, at a rather high level, yeasts and molds were present on mustard seed. The detection of *Salmonella* in mustard seed is very difficult and high dilution ratios (1:100) for mustard pre-enrichment broth are needed.[98] For the contribution of the contamination level from the other ingredients see Section 30.2.2.

30.4.3 Effect of Processing

Depending on the type of mustard being manufactured, the seeds used for making the product are either *Brassica juncea* or *Sinapis alba* but mostly a mixture of both varieties is used. German mustard is predominantly made of white seeds, whereas Dijon mustard is manufactured using *Brassica juncea* only. (Since the second world war, the use of *Brassica nigra* is abandoned and replaced by *Brassica juncea.*)

In the manufacture of German mustard, after removing the impurities from the mustard seeds, the whole seeds are added to a mixture of water, vinegar, spices, and salt and left to swell under constant stirring. Then the mixture is coarsely ground, and subsequently, the mixture is left to ferment as a result of enzymes released by the grinding process. The seeds can also be crushed dry and then mixed with water, vinegar, and salt and left for fermentation. The time for fermenting varies from 30 minutes to several hours. The mixture is then passed through corundum stone mills and ground to the desired fineness. The ground mustard is left to mature for a certain period of time, several days to a few weeks, and afterwards packed.

For the manufacture of Dijon mustard, the husks are sieved off because this product should not contain more than 2% husks. The temperature during the whole process should not be too high, especially when *Brassica juncea* is used, because the component allylisothiocyanate (AIT), which is released as soon as the seeds come into contact with water, is volatile. If the temperature gets too high the level of AIT might be too low. Therefore, in the more modern production facilities the corundum stones are cooled to avoid excessive heating. The AIT is responsible for the typical sharp pungent taste of Dijon mustard. The AIT is not present in the seed itself but it is formed as a result of enzymatic hydrolysis of the glucoside sinigrin and the enzyme myrosinase in a watery environment. Both the sinigrin and the enzyme myrosinase are present in the brown or black mustard seed.[81,114]

Mustard produced from *Sinapis alba* does not contain allylisothiocyanate. The pungency of this type of product is caused by the glucoside sinalbin, present in the white mustard seed, which is converted into p-hydroxybenzylisothiocyanate in a watery environment by the enzyme myrosinase. The p-hydroxybenzylisothiocyanate is less pungent than allylisothiocyanate, not volatile, and very unstable.

English mustard is traditionally produced by a different process. Mustard flour, which has been previously produced from dehusked seed by a dry roller milling process, is blended with other precooked ingredients. The product is acidified by citric acid and contains about 9% salt.

It will be clear that the product will not undergo any heat treatment, otherwise the enzymatic reaction will stop. Consequently, the contamination of the product itself will not be eliminated during processing. This means that the contamination originating from the ingredients and the plant will determine the microbial load of the product.

30.4.4 Spoilage Associations and Pathogen Hazards

Only acetic acid–resistant microorganisms are likely to develop in the product and cause spoilage. Although spore-formers (aerobic and anaerobic) will be present, the spores will not be able to germinate and grow because of the low pH in combination with the level of acetic acid. Other bacteria might be present but these will be inhibited and most likely decrease in number in a product with this composition, especially during the maturation period.

The most likely spoilage organisms for mustard are lactobacilli, yeasts, and molds. Some lactobacilli, especially *L. plantarum* and *L. buchneri,* are rather acetic acid resistant. Species that are heterofermentative thus can cause blowing of the product and > 10^6 g^{-1} lactobacilli have been reported in blown mustard.[75] Yeasts in general are inhibited because of the presence of the allylisothiocyanate. Nevertheless *Zygosaccharomyces bailii* was reported as the cause of spoilage of mustard produced by a Czech food company.[28] However, no information was given about the type of mustard, its pH, or acidity. Spoilage of mustard by molds is very unlikely because of the rather high level of acetic acid.

It is generally stated that AIT present in mustard is inhibitive toward growth of yeasts. Specific data are limited. When 5% Dijon mustard was added to malt broth, the number of yeasts was reduced by a factor 1,000 within 7 days incubation at 25°C. This level of mustard corresponds to 0.007% AIT in the broth. To get the same effect with mustard manufactured from *Sinapis alba,* 10% was needed.[76] This study was carried out in malt broth at pH 3.8 and 4.3. All combinations were adjusted to the same level of acetic acid (0.45%) and salt (1.27%). In another experiment, 0.01% AIT in Potato Dextrose broth at pH 4.3 without acetic acid did not inhibit yeasts, but in combination with 1% acetic acid 0.004%, AIT did inhibit the growth during an incubation period of 4 weeks at 25°C.

The addition of 0.3% to 1.5% w/w mustard to mayonnaise resulted in increased death of *S. enteritidis.*[104] Kanemaru studied the effect of AIT and mustard on the behavior of a number of bacteria. It was demonstrated that 0.8% mustard was bacteriostatic for *E. coli* and *S. aureus* and 0.2% was bactericidal for *Pseudomonas aeruginosa*. Growth was inhibited for 24 hours for *S. aureus, E. coli, Proteus vulgaris, Pseudomonas fragi,* and *Pseudomonas aeruginosa* at levels of 0.138%, 0.104%, 0.064%, 0.043%, and 0.089%, respectively. The corresponding levels for AIT were (in mg kg^{-1}) 14.5, 12.3, 6.5, 3.6, and 7.2.[74]

Isshiki studied the inhibitory action of AIT vapor against bacteria, yeasts, and molds. He showed that a reduction of 4 to 5 log could be achieved for Gram-positive bacteria and *S. enteritidis* at a concentration of 100 ng ml^{-1} and for Gram-negative bacteria at a level of about 50 ng ml^{-1}. Yeasts were affected at a level of 16 to 37 ng ml^{-1} and molds at 22 to 62 ng ml^{-1}.[73]

Because of the combination of low pH and the presence of a high level of acetic acid, growth of pathogenic bacteria will not be possible, and if pathogens are present, they will probably die off during the maturation of the product. This is supported by the absence of food poisoning incidents related to mustard.

30.4.5 Preservation

In the EC legislation on food additives[13] sulfur dioxide is allowed in mustard at a maximum of 250 mg kg^{-1} for all other types than Dijon mustard, which may contain 500 mg kg^{-1}. Sorbic and benzoic acid are permitted in mustard to a maximum of 1,000 mg kg^{-1} for the sum of both ingredients (Table 30-2).

The typical composition of mustard with its low pH and presence of > 1% undissociated acetic acid in the aqueous phase, together with the AIT present in most mustard types, is inhibitory for all pathogenic and most spoilage organisms. Lactobacilli can cause spoilage in mustard,[75] but most of the products will also be inhibitory to this organism because of the combined effect of the acetic acid and salt in the aqueous phase. To inhibit the growth of lactobacilli in those mustard types that will allow growth, benzoic acid (Table 30-2) can be added. Benzoic acid also controls the growth of yeasts. Benzoic acid is more effective than sorbic acid against lactobacilli. In historical times mustard was used as a preservative in the wine industry and for fruit juices.[46] This is still the case in Turkey for fruit juices.

30.5 MAYONNAISE-BASED SALADS

30.5.1 Composition

Mayonnaise-based salads or dressed salads are mixtures of a variety of foods with a mayonnaise base. The components may consist of chicken, meat, egg, fish, shellfish, potato, vegetables, herbs, pasta, fruits, or nuts. Apart from the mayonnaise and the main components mentioned, starch, sugar, spices, organic acids, preservatives, and flavor/colors may be present. A specific definition does not exist. Because of the vinegar of the mayonnaise base or the additional acids used, the dressed salads typically have a pH between 4.0 and 5.5. The acetic acid level in the aqueous phase is much lower than that of mayonnaise itself, and is often between 0.2% to 0.5%. Most mayonnaise-based salads are kept refrigerated to extend their shelf life. The chilled shelf life of industrial products typically is between 2 and 8 weeks.

30.5.2 Initial Microflora

The initial microflora of mayonnaise-based salads is a made up of the microbial load of the raw materials used and much depends on the microbiological status of the materials selected for the manufacture of dressed salads. The mayonnaise base typically has a low microbial count with no or a very limited contamination with yeasts and lactobacilli. Otherwise, acetic acid–tolerant spoilage organisms would be introduced with this key raw material with resultant loss of shelf life.

Considering the range of possible raw materials used, quite a variable microbial contamination may be present as shown in previous chapters and in Section 30.2.2. This was documented in a study, where *Bacilli* possibly from vegetables, in particular *B. pumilis, B. subtilis,* and *B. licheniformis* were detected in commercial salads, including chicken, ham, and potato salads, coleslaw, and pimento cheese spread, together with a range of lactic acid bacteria consisting of various species of *Lactobacillus* (*L. plantarum, L. leichmanii,* and *L. casei*), *Leuconostoc* (*L. mesentoroides, L. paramesentoroides*), and *Streptococcus.*[122]

The objective should be to use raw materials that do not introduce pathogens or significant numbers of spoilage organisms into the product. Some materials will have already a low microbial load because of pasteurization or sterilization (meat, egg, poultry, vegetables). Chicken meat, for example, can be pasteurized and delivered chilled to the processing plant, while other pasteurized materials may be put in an acid brine or salted (vegetables, cucumbers) to give them ambient stability.

For a range of natural, raw materials it is difficult to obtain these with a low count (hand-peeled cooked shrimps, vegetables, herbs and spices) and measures should be taken to reduce their counts. This can be done before arrival at the plant (steam decontamination of herbs and spices or use of spice extracts) or by treating materials at the plant. When it is not possible to eliminate spoilage organisms (for example, yeasts and lactobacilli in raw herring), it must be ensured that infective pathogens are absent by selection from safe sources. The composition and shelf life of the salads should be designed to control the expected initial contamination.

30.5.3 Effect of Processing

Mayonnaise-based salads are made by mixing (ambient or chilled) ingredients with a special thick mayonnaise or dressing. Some ingredients such as chicken or meat are cooked, diced, and chilled or bought already chilled and diced. Raw vegetables such as cabbage are well trimmed, washed, and sometimes marinated in special brines with acetic acid and preservatives to reduce their microbial load. Potatoes, carrots, and onions may be diced, blanched, or steamed and chilled. Pasta is cooked, drained, and chilled. Canned products such as fish, fruits, and tomato are chilled, taken out of the can, drained, and roughly minced. The processing of a mayonnaise-based salad essentially consists of a mixing of all ingredients with the mayonnaise base. Normally this does not include a heating step. The processing will not reduce the microbial counts and may even lead to increased counts when times and temperatures permit microbial growth. Particularly when processing is not done hygienically, this may lead to the build-up in the plant of an acid-adapted spoilage flora resulting in contamination of product and loss of shelf life.

The complete salad is packed in tubs or in larger trays for sale by the retailer (counter salads), which are closed with a sealed foil or a snap-on lid. When the salad is made from chilled components in a chilled environment, the product can be case packed, palletized, and put into chilled storage directly. Otherwise, additional chilling of the salad before palletization may be required.

30.5.4 Spoilage Associations and Pathogen Hazards

The concentration of acetic acid (from vinegar) and pH are the major contributors to the antimicrobial properties of mayonnaise-based salads.[69] These factors should be selected so that, in combination with refrigerated storage, the growth of pathogens is prevented. Acid-tolerant organisms, however, may grow and limit the shelf life of mayonnaise-based salads. In some cases pathogens have been shown to cause outbreaks of illness due to consumption of these products.

Spoilage

Yeasts, lactic acid bacteria, and molds are the most frequent cause of spoilage of stored salads because of the relatively low pH. Characteristic spoilage yeasts in coleslaws are *Saccharomyces exiguus* and *Saccharomyces dairensis*.[25] Many other yeasts such as *S. cerevisiae, Pichia membranaefaciens, Zygosaccharomyces bailii, Z. rouxii, Sporobolomyces odorus, Trichosporon beigelii, Torulaspora delbrueckii, Candida sake, Candida lambica, Candida vini,* and *Yarrowinia lipolytica* also have been shown to grow in salads.[17,22,24]

The most frequent lactic acid bacteria that multiply in dressed salads are *L. plantarum, L. buchneri,* and *L. brevis*. Less common types are *L. leichmannii, L. delbrueckii, L. casei, L. fructivorans, L. confusus, Leuconostoc mesenteroides,* and *Pediococcus damnosus*.[17,52] All of these organisms come primarily from vegetables and pickles or the processing environment. The combined use of sorbic and benzoic acids can inhibit yeasts, but these preservatives have much less effect on lactobacilli.[69] Multiplication of lactobacilli in mayonnaise-based salads may lead to high counts, which are not always accompanied by spoilage. Gas-producing lactobacilli or rope-forming strains produce more evident signs of spoilage. Molds produce visible spoilage, whereas yeasts produce off-flavor, gas formation, or colonies visible as surface growth.

A significant aspect for safety and stability is that large pieces of meat may remain at a relatively high pH within the tissues, because the acids diffuse very slowly through solid foods. If this is not prevented, eventual equilibrium may be at a pH value higher than that of the freshly made product allowing a variety of organisms to grow. Marinating meat or fish (such as herring) to reduce the pH within pieces to a safe lower value can control such hazards. Proper chilling of a mayonnaise-based salad directly after production is important to provide protection against growth of spoilage organisms or pathogens when there are still parts of the salad at a near neutral pH.

Pathogens

Foodborne illness from mayonnaise-based salads can result from the presence of pathogens or toxins in the raw materials or from growth of pathogens in the salad. Table 30-3 gives a survey of some major outbreaks. The outbreak at the European Summit Conference in Maastricht[18] clearly was the result of pathogen multiplication as numbers of *Salmonella indiana* reached levels of 10^7 g^{-1}. In the report, however, reference is made to another cold buffet for which it is claimed that a low infective dose without significant multiplication of *S. indiana* caused illness of 19 persons. The relatively high mortality in two *Salmonella* outbreaks (see Table 30-3) may be explained by contamination with *S. typhi* in the first outbreak and a very sensitive elderly population (mean age 64.2 years) at risk in the last outbreak.

Pathogens other than *Salmonella* have been associated with foodborne illness from mayonnaise-based salads as shown by *E. coli* in a potato salad on a cruise ship (Table 30-3). *Shigella* is another significant source of illness to which its low infective dose may contribute. Smith refers to at least 11 outbreaks in the US in the period 1975–1981 with over 1,500 cases of illness due to *Shigella flexneri* or *S. sonnei* caused by various salads of which eight were potato salad.[115] The latter is striking and in line with Table 30-3, where potato salad was the vehicle of infection on five occasions. Ten further reports of staphylococcal food poisoning in the US due to potato salad are reported.[27] In fact a total of 41 outbreaks caused by potato salad is listed in this publication. This high rate of foodborne illness may be due to a relatively large proportion of neutral potato in these salads and a low level of acetic acid, permitting extended survival and growth of pathogens, particularly when temperature abuse takes place. *Listeria monocytogenes* contamination of coleslaw in Canada[111] is not referred to in the table as the coleslaw mix did not contain dressing.

Growth of pathogens represents an evident safety hazard for salads with a high pH, when salads are not held at refrigerated temperatures.[47] At 22° and 32°C *Salmonella* and *S. aureus* could grow well within 24 hours in chicken salad (pH 6.1) and ham salad (pH 5.2) but no growth occurred at 4°C. Kurihara et al. demonstrated rapid growth of *S. enteritidis* at 25°C in potato, egg, and crab salads for which the pH was 5.72, 7.11, and 6.51, respectively.[77] The salads were made with 15% of homemade mayonnaise (pH 4.75), which contained 0.1% of acetic acid. With an estimated dry matter level of 30% for the salads this re-

Table 30-3 Major Outbreaks of Foodborne Illness Due to Mayonnaise-Based Salads

Country	*Year*	*Salad Type*	*Production Facility*	*Pathogen/ Toxin*	*Probable Origin of Contamination*	*Cases*	*Fatal*	*Reference*
Germany	1974	Potato salad	Industry	*Salmonella* (Typhoid)	Contamination of potato and well water; defective chill chain	417	5	70
US	1974	Potato/tuna/ egg salad; coleslaw	Country fair	*Shigella sonnei*	Contamination of salad dressing; ambient holding of salads	248		130
US	1978	Potato salad	Restaurant	*C. botulinum* type A toxin	Toxin formation in baked potatoes due to temperature abuse	8		113
Netherlands	1981	Meat/ potato	Restaurant	*Salmonella indiana*	Cross-contaminated salad from contaminated kitchen	600–700		18
US	1984	Potato salad	Cruise ship	Invasive *E. coli*		47		118
US	1987	Tuna-macaroni	Hospital	*Salmonella enteritidis*	Mayonnaise made with raw egg; ambient storage of salad	404	9	121

sults in only 0.02% of total acetic acid in the aqueous phase of the salad and thus only a trace of undissociated acetic acid to prevent pathogen multiplication (0.002% at pH 5.7 and even less at the other pH values). Evidently pH, acetic acid level, and temperature in these tests were inadequate to prevent pathogen growth.

Similarly with *L. monocytogenes* in coleslaw at pH 6.0 growth was observed at 25°C, but not at pH 5.0.[58] At pH 5.7 significant growth of *Salmonella* and *L. monocytogenes* was seen in home-style chicken salad with mayonnaise at 12.8°C, but not at 4°C.[52] In macaroni salad at pH 4.6, no growth was observed.

The deduction from the above findings is that mayonnaise-based salads with a pH above 5.0 are likely to permit growth of pathogens when not kept under refrigerated conditions. The precise conditions to prevent pathogen multiplication, however, cannot be derived from these studies as many were done with salads at pH values above 5.0, where most of the acetic acid will be present in the inactive, dissociated form. Most home-style salads made with industrial mayonnaise will have sufficient antimicrobial properties to minimize health hazards according to Erickson et al.[52] and five factors are mentioned that contribute to this. Chilled storage and an inhibitory formulation are seen as the most important ones.

Infective pathogens introduced into a mayonnaise-based salad may be killed rapidly at low pH and high temperature.[69] However, pathogens may survive for days or weeks (and well beyond the salad's shelf life) under chilled conditions.[133] Contamination with infective pathogens thus presents a distinct safety hazard for the consumer.

30.5.5 Preservation

Of the weak food acids in mayonnaise-based salads, acetic acid is the most active with antimicrobial activity against lactobacilli and yeasts, while lactic acid shows good inhibition of lactobacilli but not of yeasts.[133] The pH of the mayonnaise for the salad can be set solely by the addition of acetic and/or lactic acid, but buffering with sodium hydroxide was proposed because this allows the addition of a higher percentage of these acids at a given pH and a better microbiological stability.[45] This approach proved to work particularly well for yeasts when acetic acid and lactic acid together were incorporated in a buffered salad at pH 4.85 to 4.95 with approximately 1% acetic acid and 1% lactic acid in the aqueous phase of the salad. Yeast growth was completely inhibited for 8 weeks at 6°C in such a salad.

Because of the commonly low levels of 0.2% to 0.5% of acetic (and/or lactic) acid in the aqueous phase of commercial mayonnaise-based salads these remain vulnerable to spoilage, and sorbic acid and benzoic acid are often used to improve stability. Within the EU a maximum of 1,500 mg kg^{-1} of either sorbic acid and/or benzoic acid is permitted (Table 30-2) and in practice often a combination of sorbic and benzoic acid is used. The chemical preservation is discussed by Wit and Rombouts,[133] who demonstrate that in oil-containing products there is a critical upper pH for benzoic acid (pH 4.9) and sorbic acid (pH 5.1), above which there is no increase in effective undissociated acid because of the distribution coefficient water/oil of the preservatives and the pKa of the acids. When preservative-resistant yeasts are present the legally permitted maximum still may be inadequate as shown by spoilage of a chilled herring salad of pH 4.0 with 500 mg kg^{-1} of sorbic acid and 1,100 mg kg^{-1} of benzoic acid, which was spoiled by *Zygosaccharomyces rouxii*.[16] Depending on the initial contamination of the salad, the pH, presence of nutrients (sugars), levels of inhibitory food acids and levels and types of preservatives (if any), the typical shelf life limited by spoilage or quality loss varies from 2 to 8 weeks under chilled conditions.

Normally, mayonnaise-based salads do not permit growth of pathogens because of the acetic acid in the aqueous phase, the reduced pH, and chilled storage.[52,133] In salads with very little acetic acid and a pH above 5.0, however, pathogens may multiply, especially if the chilled chain is interrupted. The Dutch Industrial Code for Salads refers to a pH of max. 5.0, a storage temperature below 7°C, and the presence of 0.3% acid (of which 0.2% should be acetic acid), as design criteria to prevent growth of any pathogens.[12] With an assumed moisture content of 70% and 36% of the acetic acid present in the undissociated form at pH 5.0, this corresponds to $0.2 \times (100/70) \times (36/100) = 0.10\%$ undissociated acetic acid in the aqueous phase of the product, which will control pathogens under chilled conditions. Preservatives can be used in addition to the above factors, but these will contribute more to stability than to safety.

The German "Feinkostindustrie" recommends for mayonnaise-based salads a temperature below 7°C, a pH of ≤ 4.6, and 0.2% acetic acid in the aqueous phase of the product, which corresponds to *ca.* 0.1% undissociated acetic acid. Chilled storage is considered particularly important as directly after production some components may still have near neutral internal pH values. For salads where such a low pH is not well compatible with the raw materials used (shellfish) 0.3% acetic acid in the aqueous phase and a pH ≤ 5.0 is proposed, which also corresponds with 0.1% undissociated acetic acid. Evidently, safe chilled salads may be made at higher pH values with different preservation concepts (pasteurization, reduced water activity, natural preservatives, short shelf life), but a HACCP-based approach should be followed to prevent pathogen hazards.

A new approach for preservation of sauce-based delicatessen salads was followed by Bonestroo, who stabilized salads by in-pack fermentation with starter cultures of lactic acid bacteria at temperatures ≥ 42°C for a period of ≤ 8 hours, followed by cooling to below 7°C. In this way a shelf life of 5 to 6 weeks at 7°C proved possible.[22] During fermentation some increase (< 1 log) of *L. monocytogenes* and *S. aureus* was noticed, followed by a rapid decline in numbers (*ca.* 2 log).

Control over safety and spoilage hazards of mayonnaise-based salads can be summarized as a step program, which is largely based on van Schothorst[112]:

1. Determine in the design phase whether any pathogens can grow under the intended (chilled) storage conditions in the mayonnaise-based salad and select a formulation that will prevent this.
2. Determine carefully the microbiological status of all ingredients and do not use ingredients that present uncontrolled infectious pathogen hazards.
3. Use cooked, blanched, or pasteurized ingredients whenever feasible.
4. Clean and wash raw vegetables to remove all adhering dirt.
5 Dice precooked meats and poultry into small pieces, and/or marinate them in acid before mixing them with other ingredients.
6. Keep the pH as low as possible (while retaining good eating quality) by the use of sauces and dressings containing organic acids (usually acetic acid from vinegar).
7. Use strict hygiene in preparing, mixing, and storing the salads.
8. Establish a realistic shelf life for the salad by holding product slightly above the intended chilled temperatures during storage and use. For salads sold at 7°C, for example, this would mean holding at 10°C, for example, for a number of weeks followed by visual inspection (no blowing, no visible deterioration or spoilage), pH measurement (no drop in pH), organoleptic evaluation (good preservation of taste and appearance), and microbiological analysis (no excessive counts of yeasts or lactobacilli). The shelf life established at 10°C is then used at 7°C.
9. Perform a HACCP study of the manufacturing process, from raw material to consumer use, to check whether the actual product and process is in line with all the requirements that were considered critical in the design phase.

30.6 PASTEURIZED ACID SAUCES

A range of acid or acidified sauces exists, normally not acidified with vinegar or acetic acid, which are preserved by heat processing and a pH of max. 4.6. High water activity, ambient-stable sauces with a pH above 4.6 without intrinsic stability factors are low-acid foods, which are preserved by sterilization.[34] These are not considered in this section. Many of the pasteurized acid or acidified sauces are tomato-based and are sometimes referred to as pasta sauces (tomato sauces for pasta meals) or cook-in sauces for chicken and meat or stir and fry sauces for meat and vegetables. White sauces exist also. They all have in common that they are used on a host food. Because of the low pH and heat processing, the key target organisms to be controlled are acid-tolerant, spore-forming bacteria. The sauces have a long closed shelf life of a year or more, with a short open shelf life of a few days under refrigeration.

30.6.1 Composition

The composition of the sauces often includes fresh or processed tomatoes. The latter are used as canned whole, pieces, diced, or sliced tomato or as tomato puree or paste. Commonly used acidulants are citric, lactic, and malic acid and sometimes also acetic acid and phosphoric acid. Herbs and spices are used as in mayonnaise with thickeners like starches and gums. Further ingredients can be sugar, salt, condiments, flavors, and pieces of vegetables, fruits, and also meat or cheese.

30.6.2 Initial Microflora

The initial microflora of the ingredients includes those already mentioned in Section 30.2.2 for mayonnaise, but the vegetative bacteria, yeasts, or molds are easily inactivated during heat processing and not significant for product safety or stability. The ingredients like spices, herbs, tomato, and vegetables will carry a significant bacterial spore load, of which in particular the acid-tolerant types are relevant. One of the more significant ones is *Bacillus coagulans*, which is present in tomato, vegetables, dairy raw materials, and herbs and spices. For example, in whole, peeled tomatoes, sampled before canning, median values of 18 to 40 spores ml^{-1} were found in samples of three canneries.[134]

30.6.3 Effect of Processing

The acid sauces receive a heat treatment, which typically is given during processing, followed by a hot fill, and a postpasteurization process for filled containers. The heat treatment is intended to inactivate all infectious pathogens and non–spore-forming microorganisms. The acid-tolerant spore-formers, which may be able to grow in the product, either should be killed by the heat process or heat damaged to such an extent that they will not recover and grow in the product. The heat process is typically the equivalent of 10 to 30 minutes at 90° to 100°C, although milder and more severe processes exist. The latter would be the case for acid sauces with relatively high pH (close to 4.6), while much milder processes may be applied for sauces with a pH close to 4.0–4.2.

30.6.4 Spoilage Associations and Pathogen Hazards

The main spoilage organism of concern for acid sauces is *Bacillus coagulans*, formerly called *Bacillus thermoacidurans*.[20] The latter name refers to the preference for elevated temperatures and tolerance to acid conditions. *Bacillus coagulans* is strongly associated with tomato products, but may be found also in other raw materials like vegetables, spices, or dairy products. *B. coagulans* causes flat-sour spoilage, ie, acid formation and no gas, when the spores germinate and grow in acid sauces. The resultant drop in pH typically is small (about half a pH unit) but may also be nil,[108,134] and can be accompanied by a typical taste. Because little information has been published on spoilage of acid sauces, many of the preservation processes are derived from those applied for tomato and other acid or acidified products. An interesting example is a study on spoilage of canned, whole peeled tomatoes in juice for which in the 1960s a heat process equivalent with 0.7 minutes at 121.1°C was proposed by the National Canners Association (NCA) to control *B. coagulans* in products with a pH of 4.5, when acidification with citric acid was not yet permitted.[95] It was later established that spores of *B. coagulans* did grow well in tomato juice, acidified with citric acid to pH 4.45, when heated for 10 minutes at 90°C, but no growth occurred when the pH was reduced to 4.31.[134] Without any heat, the spores could germinate and grow at pH 3.8 when the inoculum was sufficiently high with 640 spores ml^{-1}. The combination of mild heat and reduction of pH to 4.3 apparently caused sufficient heat damage of the spores to ensure product stability under conditions that were well below those recommended earlier by the NCA. The feasibility of the reduced heat process was documented in a process for peeled tomatoes equivalent to 1.56 minutes at 100°C, which did not give any spoilage when challenged with spores of *B. coagulans* ATCC 8038.

Spoilage of tomato products may also be caused by butyric anaerobes such *as Clostridium pasteurianum* or *C. butyricum*. This is a rarer type of spoilage, first described for tomato juice, and causing a bad butyric smell of the juice. Bowen et al.[23] studied spoilage of canned tomatoes and showed that acidification with 0.1% citric acid to pH 4.3–4.4 and heating to a can center temperature of 200°F (93.3°C) was adequate to control contamination with spores of *C. pasteurianum*. This finding is in line with the NCA published Thermal Death Curve for *C. pasteurianum* with 10 minutes at 200°F at pH 4.5.[93] An alternative way to achieve stability was acidification with 0.2% citric acid to a pH of 4.1 or less and heating to 90°C.[23]

Leaker spoilage by lactobacilli or yeasts may occur when cans or jars are not hermetically closed, or when heat-resistant molds survive the heat process. This may introduce a safety hazard because of a local increase in pH and an unexpected botulinum hazard.[66] Otherwise neither *B. coagulans* nor other spoilage organisms of acid sauces present a hazard.

30.6.5 Preservation

Clostridium pasteurianum is less heat resistant than *B. coagulans*; heat processing of pureed tomatoes at pH 4.3 to 4.4 to a center temperature of 200°F (=93.3°C) prevented spoilage.[23] The NCA indicated that a process equivalent to 10 minutes 93.3°C would be adequate for butyric anaerobes in products with a pH above 4.3 and 5 minutes when the pH was between 4.0 and 4.3.[95] Other sources refer to a product temperature of 95°C when the pH is between 4.2 and 4.5, whereas heating to 84°C may be adequate at a pH below 4.2. For acid sauces this spore-forming organism normally is of little significance as the heat process required to control *B. coagulans* is well above that for *C. pasteurianum*.

Bacillus coagulans spores are rather variable in heat resistance. Published D-values in tomato puree at a pH of 4.3–4.5 range from 9.0 to 12.3 minutes at 90°C[108] to 0.23 minutes at 121°C.[135] Also Put and Wiebenga[102] found a high heat resistance for spores of *B. coagulans* strain Sp. 33 in phosphate buffer of pH 6.8 with a D_{110} of 2.4 minutes. Even a D_{121} of 3 minutes was reported.[93] The process proposed[108] for crushed tomato at pH 4.5 was 2.56 minutes at 110°C. The FDA recommendation for products at this pH is 310 to 500 minutes at 95°C (equals *ca.* 10 to 15 minutes at 110°C), which is a more severe process.

The heat resistance of other acid-tolerant sporeformers in tomato juice was investigated[109,110] because there was concern that growth of these *Bacilli* may raise the pH of the juice and permit spores of *Clostridium botulinum* to grow and produce toxin. The D_{100} for *Bacillus subtilis* was 5.7 minutes and for *B. licheniformis* 5.9 minutes, with z-values of 14° and 14.2°C. Under aerobic conditions, both *Bacillus* species could grow in juice at pH 4.4 and raise the pH to 4.8. Under anaerobic conditions both organisms could not germinate and outgrow in juice at pH 4.4. It was concluded that spores, which may survive the commercial heat process for tomato juice of 10 to 60 minutes at 100°C, will only grow if aerobic conditions are present in the can.[110] Based on these findings, both *Bacillus* spp. may not be very relevant as spoilage organisms for acid sauces, although *B. licheniformis* is considered important for acidified canned vegetables.[97]

The key issue in many existing processes to control *B. coagulans* in acid sauces is that it is not always clear whether the proposed process is aimed at inactivation of all spores (which will require very severe processes) or will inactivate some spores and damage the rest to prevent them from germination and growth in the product because of its reduced pH and the natural weak acids present. A further aspect to consider is that not all products will be exposed to temperatures that allow spoilage. Temperatures of 35° to 45°C are optimal for *B. coagulans* growth in acid sauces, but in temperate climates these temperatures will be rare. Prompt cooling after heat processing can prevent the occurrence of such temperatures. The following example may demonstrate the influence of storage temperature.[15]

A tomato-based pizza sauce with a pH of 4.5, a_w of 0.98, and 500 mg kg^{-1} of sorbic acid was preserved by heating to 95°C for 2 to 5 minutes followed by hot fill at 80°C in aluminum foil pouches and a postfilling pasteurization for a few minutes at 85°C. This sauce had a documented shelf life of 6 months at ambient temperatures of 25°C with no evidence of spoilage. When samples of the same sauce were stored at 37°C they spoiled within 2 weeks because of growth of *B. coagulans*. A more detailed study showed an initial load of *B. coagulans* spores of 50 to 100 g^{-1} of the sauce gave no spoilage at all within 24 weeks at 15°, 20°, 25°, 50°, and 55°C. At 37° and 42°C *B. coagulans* caused a pH drop to 3.9 and spoilage of the sauce within 10 days. At 30°C, spoilage was noticed after 4 to 6 weeks and at 46°C after 2 weeks.[15] The example shows that the spoilage of such an acid sauce can be strongly temperature dependent and a sauce that may be stable in the temperate conditions could spoil when distributed at warmer Mediterranean conditions. For the latter case, heat processing to a temperature above 100°C may have been required.

Thus, for acid sauces, a range of heat processes may be applied, ranging from a few minutes at 90°C to well over 110°C depending on inactivation or heat damage of acid-tolerant spores present. For development of any new process, carefully establishing the impact of product composition, pH, weak acids, initial spore load, the overall heat process, and intended storage temperatures on the control of the target organism is required. In some countries the use of preservatives (sorbic or benzoic acid) is permitted, which may further contribute to stability. Good understanding of these factors may result in significantly reduced heat processes and better product quality. Care should be taken for sauces with neutral meat, vegetable, or cheese particulates to ensure that these particulates are properly adjusted to a pH value below 4.6; otherwise, a botulinum hazard may be created in pockets with elevated pH. For pH adjustment, the type of acid may not be not very significant because at pH 4.5 no difference was noted in inactivation of *B. coagulans* spores at 105° or 110°C after acidification with lactic, citric, acetic, malic, or hydrochloric acid. With further reduction to pH 4.2, this changed and acetic and lactic acid gave faster inactivation.[86]

30.7 CONCLUDING REMARKS

The products discussed in this chapter are characterized by a reduced pH, often achieved with weak acids such as acetic acid or lactic acid. This combination has given industrial products significant protection against pathogen growth and foodborne illness, but the use of contaminated raw materials, such as raw egg and/or inadequate control over equilibrium pH of final products has permitted major outbreaks of food poisoning. Currently, the safety aspects of these products are well understood and the importance of using pasteurized egg in all emulsified products is generally recognized by food hygiene professionals, whether products are industrially prepared or made in large kitchens. The application of HACCP will add to the product safety of all these products and risk analysis techniques as applied by Whiting and Buchanan[132] for the *Salmonella enteritidis* hazard of homemade mayonnaise will give even better understanding of the significance of the key factors to product safety. In view of the preference for milder and less processed products there is, however, still a need to establish more accurately safe combinations of pH and undissociated, weak acids for emulsified and nonemulsified dressings and sauces. Otherwise, it may occur that acetic acid in a formulation is replaced with lactic, citric, or another weak food acid, without due consideration of loss of antimicrobial activity associated particularly with undissociated acetic acid. When combined with an increase in pH to values of 4.5 and above, such change may lead to loss of intrinsic stability and recurrence of known product safety problems. Therefore, within our company a microbiological expert system, MIDAS (Microbiological Design Approval System), was developed, which assists companies in developing dressings that are safe because of an integrated evaluation of raw material, processing, and shelf life requirements, resulting in an approved safe design.[42]

With respect to product stability, there will be options for application of novel preservation technologies, such as natural antimicrobials and high pressure. For an up-to-date overview of these new technologies, the reader is referred to *New Methods of Food Preservation.*[64] Nisin inhibits most lactic acid bacteria in beer,[96] and its application for inhibition of spoilage lactobacilli in dressings was reported.[92] Nisaplin at 200 mg kg^{-1} (equivalent to 5 mg kg^{-1} of nisin) gave full inhibition of 10^4 g^{-1} *Lactobacillus brevis* subsp. *lindneri* inoculated into ranch dressing with a pH of 3.8, 4.0, and 4.2 at 26°C. In the dressing at pH 4.2 without nisin, the inoculated lactobacilli grew in 30 days to 10^8 g^{-1}. For dressings, the use of nisin will be granted in the US to inhibit lactobacilli, although the price may delay its introduction on a commercial scale.

Nisin was also studied for inhibition of *B. coagulans*, and a level of 1 IU ml^{-1} nutrient agar gave inhibition of 10^3 spores per plate. Combinations of high hydrostatic pressure, reduced pH, and nisin gave further inactivation of spores. A 6 log reduction was achieved at 70°C with a pressure of 400 Mpa in pH 4.0 buffer for 30 minutes, when plated in nutrient agar with 0.8 IU nisin.[107]

Natural antimicrobials from extra virgin olive oil may present an additional option to control pathogens in oil-based sauces.[103]

It is expected that a better understanding of the traditional preservation processes and the application of novel preservation technologies will allow the development of further new and safe products. Much care must be taken in this process to prevent new preservation options from providing new ways of transmitting foodborne illness, as more natural may not necessarily mean more safe.

31.1 INTRODUCTION

Over the past two decades, the soft drink industry has been booming,[45,188,207] with annual growth approaching 10%. Production by volume of soft drinks, including mineral waters, has been predicted to reach 50bn liters in 1997.[93] Expansion has been global,[207] growth being particularly strong in the less-developed markets of Southeast Asia.[45] Carbonated beverages, despite rising consumption of fruit juices, still account for about 50% of the market.

Current trends in the mature markets of the developed world are toward healthier "back-to-nature" styles of soft drink,[188] including a proliferation of "New Age" drinks, sports drinks, fiber drinks, flavored ice teas, and fruit-flavored mineral waters that blur the traditional distinctions between beverages and exotic fruit drinks. Demand for traditional fruits is likely to outstrip supply,[188,189] leading to increased use of more exotic fruit juices. The market for fruit juices is currently dominated by Europe and the United States (US). Five major markets, US, Germany, United Kingdom (UK), Netherlands, and France, account for 65% of total world imports,[188] the majority of this trade being in frozen concentrated orange juice (FCOJ). Orange represents 59% to 73% of US imports, followed by apple/pear 16% to 24%, and pineapple 7%.[188]

Much has been written concerning the microbiology of soft drinks and fruit juices. Knowledge of likely spoilage organisms in these products has been widely disseminated, both within the industry and in academic circles.[21,50,176,204,282] Yeasts, such as *Zygosaccharomyces bailii*, remain the principal organisms of contention because of their physiology and phenomenal resistance to chemical preservatives.[130]

However, the technology of soft drinks manufacture has progressed, with possible new preservation technologies including ultra high pressure, irradiation by ultraviolet or optical wavelengths, processing in sterile environments and heat treatments; the

ultimate goal being fast, low cost, aseptic filling. There has also been a proliferation of new packaging materials and formats, including plastics, metal-foil, and cardboard laminates.

Despite modern technology, spoilage of soft drinks and fruit juices continues to occur. While microorganisms and raw materials remain unaltered, manufacturing practice is undergoing change motivated by increasing competition, new technology, and public demands for more "natural" products.[93] New technology itself has created new microbiological problems; an example being the plastic PET (polyethylene tetraphthalate) bottle. This is an attractive, light, and convenient packaging format, able to contain carbonated products, and very popular with consumers.[198,249] However, it has the twin disadvantages of allowing oxygen permeation through the plastic and of not being able to withstand pasteurization temperatures without distortion, thus requiring aseptic filling or addition of preservatives.

Throughout the developed world, the public is becoming more aware of the presence of chemical residues in foods. This may have arisen from agricultural overuse of biocides that persist in the food chain, but has had the result of inducing public antagonism to all perceived chemical adulteration of foods. In parallel has come approval and demand for more herbal and "natural" products and processes.[93] Legislation has, in general, reflected public concern and political necessity rather than science, and has moved toward removal of preservatives and to reduction in permitted levels. Preservative legislation varies widely across the world. In the European Community (EC), current limits in soft drinks are 300 ppm sorbic acid or 150 ppm benzoic acid,[14] whereas in the US these preservatives have generally recognized as safe (GRAS) status and their concentration is, therefore, only limited by taste considerations. One of the most significant spoilage organisms of soft drinks and fruit juices is the yeast *Zygosaccharomyces bailii,* which can grow in excess of 500 ppm sorbic acid. Permitted concentrations of preservatives are already so low as to render some products microbiologically unstable. Such public and legislative trends are likely to result in increased incidents of microbial spoilage.[20]

31.2 COMPOSITION AND CHARACTERISTICS OF FRUIT JUICES AND SOFT DRINKS

31.2.1 Definitions

Fruit Juices

Fruit juices are the unconcentrated liquids extracted, usually by pressure, from mature fruit. Legal definitions of fruit juices, permitted additives, and treatments vary between countries and are reviewed by Pollard.[206] The EC Directive states that fruit juices are the juices extracted from fruit by mechanical processes, fermentable but unfermented, having the characteristic odor, color, and flavor typical of the fruit from which they come.[206] Pectolytic enzymes may be added to certain fruits, such as raspberries, blackcurrents, strawberries, and plums, prior to pressing, to break up the cell structure and enable free flow of juice.[79,120] Pressed juices often contain large amounts of insoluble solid material and may require clarification. Ascorbic acid (vitamin C) may be added to juices (Figure 31-1) as an antioxidant.[206] Juices may be sold fresh, concentrated by evaporation, preserved by pasteurization or more rarely, in the case of grape juice, preserved at low temperature with sulfites.[269]

Fruit Juice Concentrates

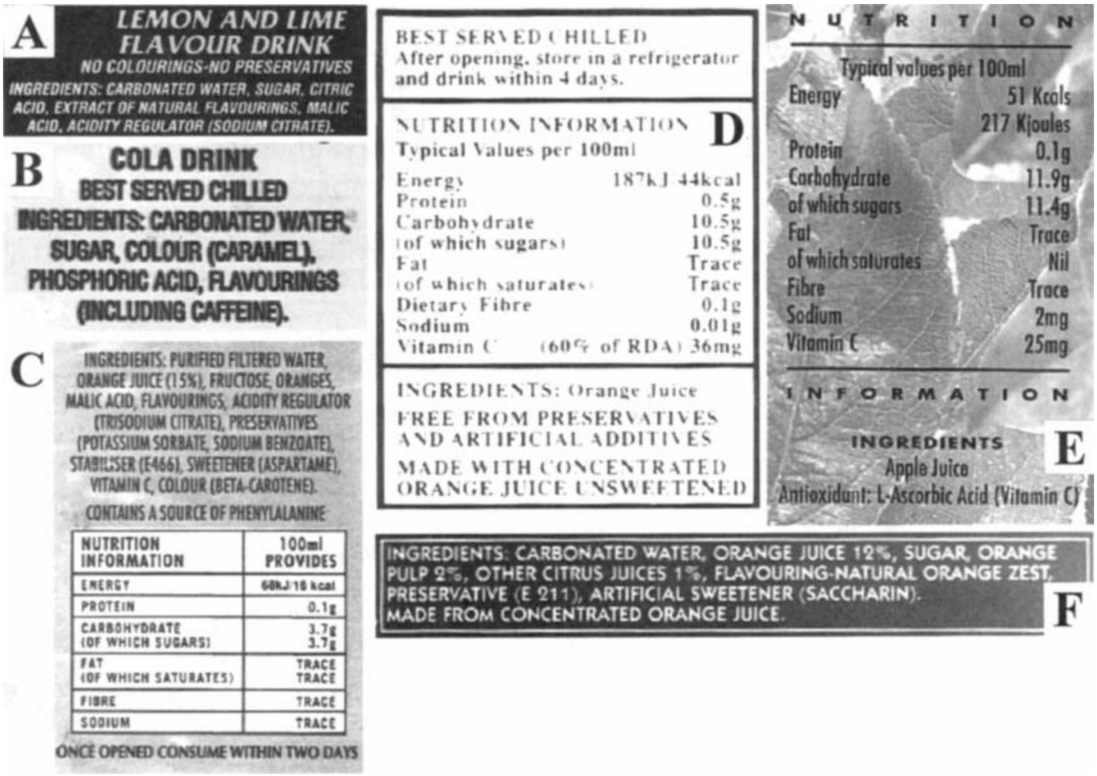
Concentrates are prepared from juices by water evaporation under vacuum at elevated temperatures. Volatiles such as citrus essences are recovered by fractionation and blended back into concentrates.[214] Obvious advantages of concentration are volume reduction in storage and shipping and microbiological stability if sufficiently concentrated and chilled. Much of the world trade in fruit juices involves concentrates, notably frozen concentrated orange juice (FCOJ).[133]

Fruit Nectars

Nectars are partially diluted pulpy liquids prepared from juices or concentrates. The EC Directive[206] considers nectars to be unfermented but fermentable products, obtained by the addition of water and sugar to fruit juice, concentrated fruit juice, or fruit puree. Many fruits juices are highly acidic and considered inedible in their natural state, eg, juices from sloes, passionfruit, or gooseberries, and their nectars must contain a minimum of 25% juice. Nectars from less acidic, edible juices, such as citrus or apples, must contain a minimum of 50% juice.

Soft Drinks

Soft drinks is a term encompassing a wide variety of products, fruit-based or otherwise, carbonated or still. This diversity has caused regulations concerning soft drinks to be more concerned with permitted additives rather than defined contents. Still soft drinks are predominantly fruit based and include fruit drinks, fruit juice drinks, and fruit squashes. More recently, a number of still tea-based beverages have been marketed. These range from products



LEMON AND LIME FLAVOUR DRINK
NO COLOURINGS-NO PRESERVATIVES
INGREDIENTS: CARBONATED WATER, SUGAR, CITRIC ACID, EXTRACT OF NATURAL FLAVOURINGS, MALIC ACID, ACIDITY REGULATOR (SODIUM CITRATE).

COLA DRINK
BEST SERVED CHILLED
INGREDIENTS: CARBONATED WATER, SUGAR, COLOUR (CARAMEL), PHOSPHORIC ACID, FLAVOURINGS (INCLUDING CAFFEINE).

INGREDIENTS: PURIFIED FILTERED WATER, ORANGE JUICE (15%), FRUCTOSE, ORANGES, MALIC ACID, FLAVOURINGS, ACIDITY REGULATOR (TRISODIUM CITRATE), PRESERVATIVES (POTASSIUM SORBATE, SODIUM BENZOATE), STABILISER (E466), SWEETENER (ASPARTAME), VITAMIN C, COLOUR (BETA-CAROTENE).
CONTAINS A SOURCE OF PHENYLALANINE

formed from direct leaf extraction to those made from spray-dried tea powders. Ready-to-drink teas are slightly sweetened and are typically flavored with lemon or other fruits.

Carbonated Soft Drinks

This category includes colas, sparkling fruit drinks, mixers such as tonic or ginger ale, lemonade, carbonated teas, shandy, and cream soda. Carbonation involves dissolving carbon dioxide in the beverage under slight pressure, forming sparkling beverages. It is measured in Volumes Bunsen, CO_2 volumes at 0°C and 1 atm, dissolved per volume liquid, or in grams CO_2 dissolved l^{-1} ($1.96\ g\ l^{-1} = 1$ volume[172]). Carbonation of soft drinks is typically around 3 volumes, varying from 1.5 in sparkling orange to 5 in soda water. Low carbonation can be achieved by carbonate addition but more usually by pressurized CO_2 addition during bottling.[279] Soft drinks may also contain additions of sugars, vitamins, acids and their salts as acidulants and acidity regulators, flavorings, artificial sweeteners, colorings, emulsifiers and stabilizers, antioxidants, and chemical preservatives (Figure 31-1). Additives and their concentrations vary widely depending on legislation pertaining to the area of sale or production.

Alcoholic "Soft" Drinks

Alcholic "soft" drinks were launched on the UK market in 1994–1995. Alcoholic soft drinks typically contain 4% to 6% ethanol in a fruit-based soft drink. The majority are not fermented products, and their microbiology resembles that of soft drinks.

31.2.2 Chemical Composition

Fruit juices and soft drinks are essentially aqueous chemical solutions, sometimes containing a few percent suspended solids. These range from the simplicity of a lemonade, carbonated water, sugar, and citric acid, to the complexity of mixed fruit juices. Characteristic of all soft drinks and fruit juices are low pH and a fermentable sugar content (zero-sugar drinks excepted).

pH, Buffering Capacity, and Titratable Acidity

pH is the negative log of the hydrogen ion concentration. pH indicates only the free H^+ concentration and does not indicate the size of the proton reservoir held combined by buffering. Buffering capacity is a measure of the ability of a solution to resist change of pH. In soft drinks, buffering capacity indicates the capacity of a beverage to maintain pH value, against changes induced by microbes (Figure 31-2). Titratable acidity measures the amount of alkali needed to titrate the acids present and is usually expressed as equivalents of citric acid in g l^{-1}. Almost all buffering in soft drinks and fruit juices is due to organic acids and acidulants.

In soft drinks, the taste threshold for acidity is in the region of pH 3.7–4.1,[106] sourness increasing with lower pH. However, perception of sourness is more closely linked with titratable acidity and buffering capacity than absolute pH value. The pH of most fruit juices (Table 31-1) ranges from 2.5–4.0,[119] limes being exceptional at pH 1.6–3.2 and pineapple averaging pH 3.8–4.0.[122] After long storage, the pH of apples may rise to pH 5.0.[271] Soft drinks have pH values largely in the range 2.5–3.0, except for diet/light formulations, pH 3.2–3.5. Tea-based beverages pH values tend to be slightly higher, pH 3.2–4.2.

Sugars

Fruits are designed to be eaten, appealing in color, scent, and sweetness. Hexose sugars constitute the largest soluble fraction of fruit juices. Fruit juices contain *ca.* 10% sugar (Table 31-1). Strawberries and raspberries contain less while grape juices contain up to 25% sugar. The perceived sweetness of fruit juices is modified by presence of acids and the sugar type, fructose tasting sweeter than glucose, for example.

The principle sugars in fruit juices are fructose, glucose, and sucrose. Proportions of sugars vary with fruit variety and ripeness (Table 31-1). Apples contain a higher proportion of fructose,[148] traces of xylose,[308] and moderate amounts of sorbitol, about 4 g l^{-1}, in contrast to pears, which contain up to 20 g l^{-1} sorbitol.[277] Grape juices contain more glucose, particularly at earlier stages of ripeness,[307] traces of pentoses,[6] and negligible sucrose. Apricot, peach, and pineapple juices are particularly rich in sucrose.[267] Changes occur in sugar composition during storage, notably the inversion of sucrose to glucose and fructose.[28] Up to 15 g l^{-1} sugar may be added to fruit juices for modification of perceived acidity.[206]

Soft drinks contain sugars at similar concentrations to fruit juices, typically ranging from 7% to 12%.[279] Concentration of sugar in soft drinks is customarily measured in degrees Brix, the w/w percent-

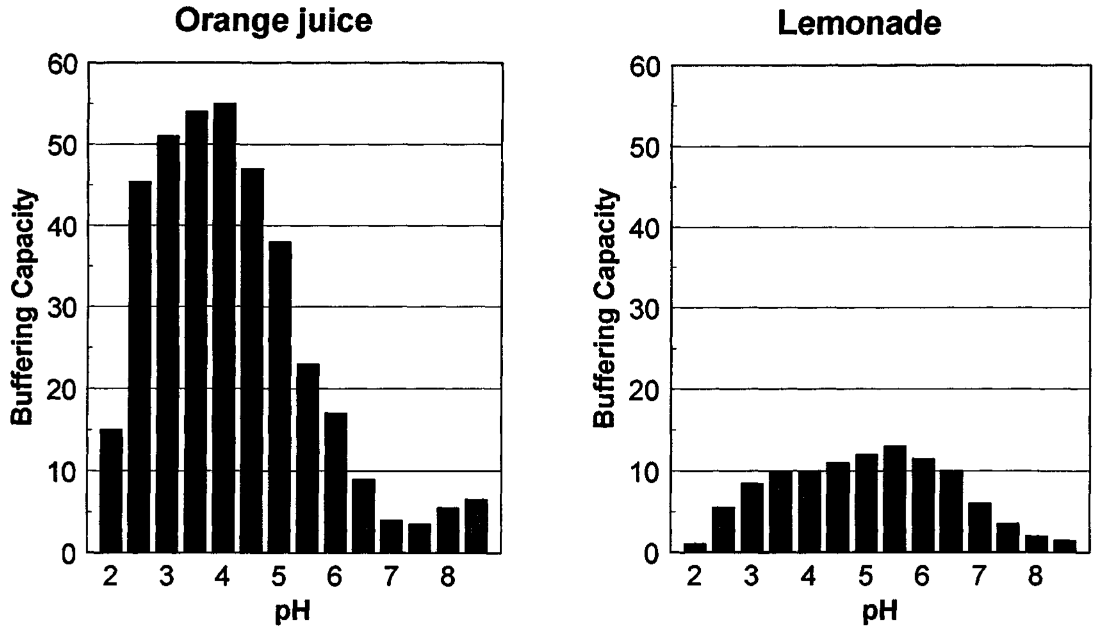

Figure 31-2 Buffering Capacity of a Fruit Juice, Orange, and a Soft Drink, Lemonade. Samples were de-carbonated, the pH was raised to 9.0 with NaOH, and titrated with 0.1 M HCl. One unit of buffering capacity is the amount of protons (m moles) required to change the pH of 1 liter by one pH unit.

Table 31-1 Sugar Content, pH Range, and Major Acids Present in Various Fruits

Fruit	*Sugar (w/w%)*	*pH Range*	*Major Acids*
Apple	10–14	2.9–4.5	Malic, citric
Apricot	6–7	3.1–4.5	
Cherry	9–13	3.7–4.4	Malic citric
Grape	15–25	2.9–3.9	Tartaric, malic
Grapefruit	8.8–10.2	2.9–3.6	Citric
Guava	9	3.2–4.2	Citric, malic
Kiwifruit	12	*ca.* 4.0	
Lemon	8–9	2.0–2.55	Citric
Lime	9	1.6–3.2	Citric
Mango	15–17	*ca.* 4.35	Citric, tartaric
Orange	9–12	2.6–4.3	Citric, malic
Passionfruit	15	2.6–3.4	Citric, malic
Peach	8–9	3.6–4.0	Malic, citric
Pear	9–11	3.0–4.5	Malic, citric
Pineapple	12–15	3.1–4.0	Citric, malic
Plum	9–11	3.0–4.5	Malic, quinic
Raspberry	6–7	2.5–3.1	Citric
Strawberry	5–6	3.0–3.4	Citric

age of the sugar concentration in solution. Sugars may be added in dry granulated form (sucrose) or as sugar syrups, usually 67° Brix. These can be of sucrose, glucose-type syrup produced from maize, or high-fructose glucose syrup produced from wheat.[29] Diet formulations of soft drinks contain less sugar (*ca.* 1%), the sweetness balance being made up with artificial sweeteners.

Acids, Acidulants, and Acidity Regulators

The characteristic taste of a soft drink is imparted by a balance of sweetness, from sugars, with acidity from various organic acids. After sugars, acids constitute the second largest constituent of fruit juices and soft drinks. Acids comprise various organic acids from fruit juices and acidulants. Acidulants are acids added to lower the pH; acidity regulators are the salts of these acids, added to increase the pH. The result is a solution of defined pH, containing organic acids and their salts, the proportions depending on the pH value. Concentrations and types of acids present in juices are characteristic of the fruit. Malic acid predominates in apples, cherries, and plums; citric acid in citrus fruits, such as orange, lemon, grapefruit, and in black currants and strawberries; and tartaric acid is unusual and is characteristic of grape juices. Sizable fractions of other acids may be present, such as quinic acid in apples. Ascorbic acid is also present. The concentrations of acids in fruit juices are usually of the order of 1%.[103] Malic acid in apples can range from 0.18% to 1.4%.[148] Berry fruits tend to be higher in acidity, notably black currant containing 4% citric acid.[99]

Acidulants added to soft drinks are often identical to those in fruit juices; citric, malic, and tartaric acids predominating. Different acids have different taste characteristics, such as the light, fruity character of citric acid, a fuller, smoother flavor for malic acid, and a sharper flavor for tartaric acid.[279] Other acids used are phosphoric acid in cola-type soft drinks, lactic acid for a smooth flavor, acetic acid in nonfruit drinks, fumaric acid, and adipic acid, notably in the US market.[265,279] Amounts used in soft drinks, in citric acid equivalents of titratable acidity, are of the order of 1–4 g l^{-1}.

Nitrogen-Containing Compounds

Fruit juices in general contain low concentrations of nitrogen-containing compounds: ammonium ions, amino acids, and peptide fragments. Orange juice contains 3–4 g l^{-1} amino acids, the majority of this being proline. Ammonium ions are seldom present at more than 25 mg l^{-1}.[103] Apple juices contain about 1 g l^{-1} amino acids, the majority being asparagine, with lower amounts of aspartic acid and glutamic acid.[17,43] Grape juices are variable in nitrogen content, ranging from 90–840 mg l^{-1}, as equivalents of ammonium ions.[174] Grape nitrogen content was directly correlated with nitrogen in the soil and application of fertilizer.[30,199] Amerine and Ough[5] examined 29 grape juices that averaged 440 mg l^{-1}. Some 80% of this comprised amino acids, although proline again predominated.[123] Soft drinks contain nitrogen-containing compounds derived from fruit components, and from organic flavorings. The artificial sweetener, aspartame, can break down to yield phenylalanine.

Phosphates

Phosphates are present in relatively low concentration in most soft drinks and fruit juices, the notable exception is colas acidified with phosphoric acid. Phosphorus contents of 110, 210, and 180 mg kg^{-1} have been reported in apples, oranges, and peaches, respectively.[84] Higher phosphate levels have been reported in grape musts, 200–500 mg l^{-1},[4] variations are because of fruit variety, ripeness, growing region, and fertilization practices.[107,144]

Salts and Trace Elements

Fruit juices are characteristically rich in potassium but contain relatively low concentrations of sodium, calcium, magnesium, iron, copper, and zinc, compared with whole fruits. This is due to the adsorption of inorganic nutrients to cell wall materials of fruits.[267] Potassium is present in apple juice at *ca.* 1 g l^{-1}, sodium, calcium, and magnesium in the range 16–131 mg^{-1}, iron at 1.5–4.7 mg l^{-1}, and manganese, copper, and zinc at 0.22–0.41 mg l^{-1}.[43]

Antioxidants and Oxygen

Presence of oxygen in fruit juices can cause adverse effects. Oxidized juices lose their freshness and acquire a dull, tired taste. Citrus oils are very susceptible to oxidation to terpines, d-limonene having a harsh turpentine taste.[119] Oxidation also causes color changes, with browning of apple juices being a recognized problem.

In soft drinks and fruit juices, oxygen levels are likely to be low, minimized through the use of hot filling, pasteurization, and antioxidants.[119] If products are in nonoxygen-permeable packaging and filled to minimize headspace, oxygen levels are also likely to be below that needed for mold growth. PET plastic bottles allow slow oxygen permeation,[219] dissolved levels *ca.* 1–3 ppm are common, and require addition of antioxidants for prolonged shelf life. Antioxidants react preferentially with the available oxygen, thereby reducing product oxidation until the antioxidant is consumed. Natural antioxidants are present in many fruits, eg, tocopherols present in citrus peels.[288] Organic acids also act as antioxidants or in synergy with antioxidants.[106] Ascorbic acid (vitamin C) is an excellent antioxidant and is present in orange juice at between 260 and 840 ppm.[116] The German RSK (Richwerte und Schwankungsbreiten bestimmter Kennzahlen) guidelines stipulate a minimum of 200 ppm in single-strength orange juice.[103] Other juices such as apple, contain less than 100 ppm although 318 ppm has been reported.[148] The high susceptibility of apple juices to rapid oxidative browning has led to the practice of adding ascorbic acid (500 ppm) to fruit during milling or to the expressed apple juice.[148]

Sulfites, while recognized as preservatives, have a long history as antioxidants, maintaining fresh aromas in juices.[162] In the presence of metal ions, sulfites are preferentially oxidized to sulfates. Other antioxidants, BHA (butylated hydroxyanisole), or BHT (butylated hydroxytoluene) are used to protect oil-based flavors before addition to beverages.[279] These may be present in soft drinks, diluted with flavors, to a final concentration around 1 ppm.

Preservatives

Preservatives permitted in soft drinks include sorbic acid and sorbate salts, benzoic acid and benzoate salts, SO_2, sulfite, bisulfite, and metabisulfite salts, and esters of p-hydroxybenzoic acid, and parabens.[50] The antimicrobial activity of preservatives in drinks is discussed in Section 31.5.2.

31.3 THE MICROBIOLOGY OF THE MANUFACTURING PROCESS

31.3.1 The Manufacturing Process

Fruit juice manufacture typically occurs close to the areas of fruit production, to minimize transport costs and deterioration of fruit. After delivery, fruit is processed to remove leaves, stems, and other foreign items; washed; milled; and crushed (Figure 31-3).[165] Certain fruits may require destoning. The juice is usually extracted by pressure and the solids removed in "juice polishing" operations that may involve clarification, decanting, centrifugation, or filtration. Pectolytic enzymes may be added to the fruit mash[79,120] to improve extraction and aid clarification. Single-strength juice is bulky, requiring large storage volume and incurring high transportation costs. Juices are therefore commonly concentrated at the site of production. Juice is heated to just below 100°C, vacuum is applied, and excess water removed by evaporation.[212,214] Volatile components, such as aroma oils, are recovered and added back to concentrates after cooling. Depending on how the final concentrate will be handled, one of three options can be pursued: (1) Add preservatives (eg, benzoic acid, sulfite, or combinations) and fill into drums for ambient storage; (2) fill into drums and freeze (frozen concentrated orange juice exported from Brazil accounts for the majority of juice imported into the US[133,188]); and (3) aseptically fill into sterile drums for ambient storage.

Soft drinks manufacture is essentially a simple operation of dissolving flavors, acid, and sugar in water and dispensing into appropriate containers (Figure 31-4). Sugar either comes as granules and is dissolved to make a 67° Brix syrup or is ready-supplied in the syrup form. During sugar dissolving, temperatures of typically 85°C/30 seconds are employed. Separately, other components of the product are combined (ie, fruit juice, flavors, acid, and antioxidants). This is mixed with simple sugar syrup to form the final syrup. This syrup (approximately 40–50° Brix) is proportioned with water to produce a final product of approximately 7–10° Brix. This is filled into the relevant consumer packaging, eg, can, glass, or PET bottle, sealed, and entered into the distribution system.

Microbial stability may be achieved in a number of ways. Products may be sterilized in-pack using a

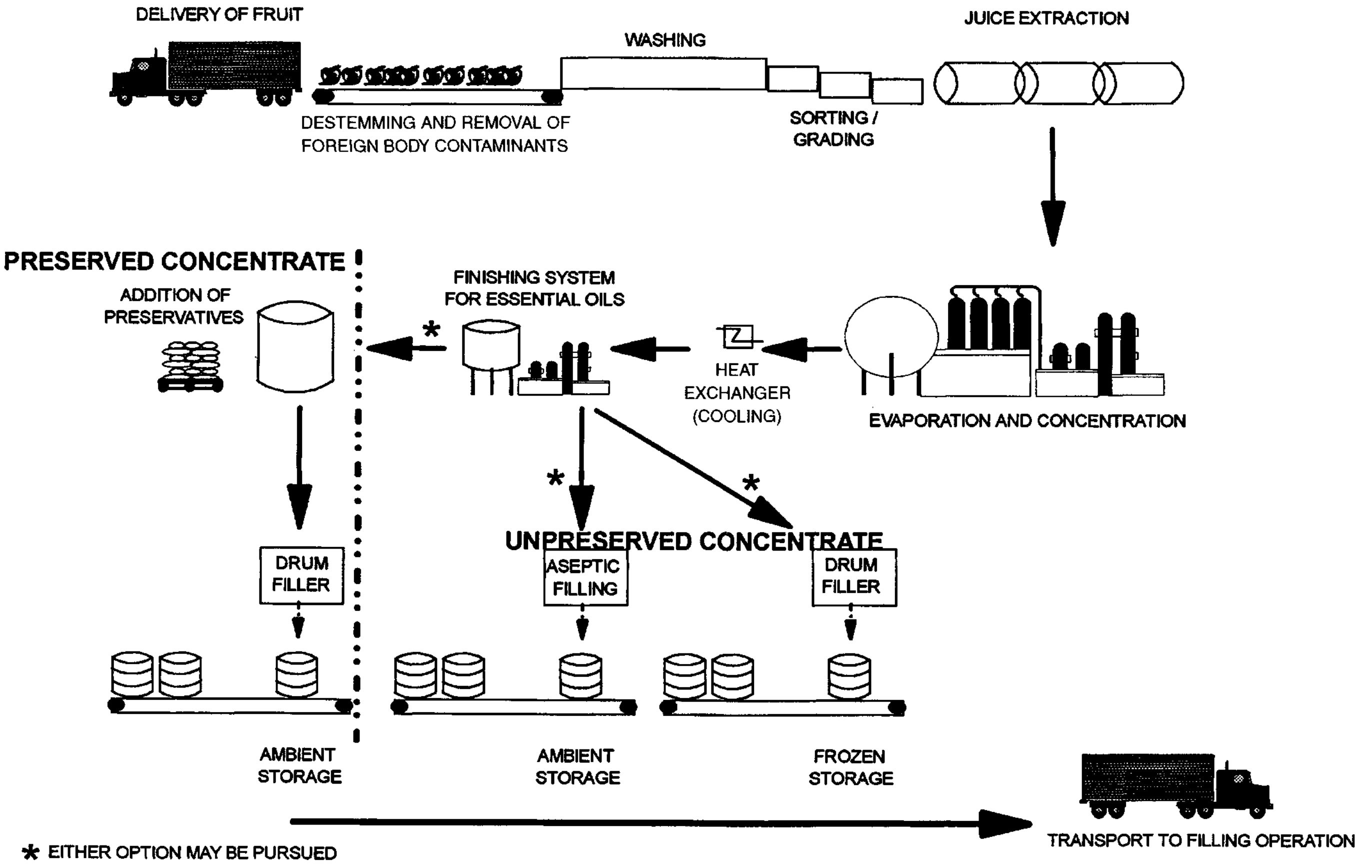

Figure 31-3 Schematic Diagram of a Fruit Juice Processing Plant.

Tunnel pasteurizer, sterilized in-line using a Plate pasteurizer and aseptically filled, in-line pasteurized and hot-filled, preservatives may be added, or the product given a flash, in-line pasteurization to lower the microbial load, in addition to use of preservatives. Products, such as fresh-pressed fruit juices may be preserved by chill storage for a limited time.

31.3.2 The Microbiology of Production

Sources of Infection

Fruit and fruit juices are major sources of yeast and mold contamination. The surfaces of fresh fruit are often contaminated with large numbers of molds,[194] particularly where the surface has been broken. Mold ascospores are widely distributed in soil; and fruits coming into contact with the ground are particularly prone to contamination with ascospores.[183] Fruit, at all stages of development, represents a major natural habitat for many species of yeast.[78] Shriveled mummified fruits, in particular, are excellent environments for osmophilic yeasts, many of which can spoil fruit juices.[27,68,286,287] Consequently, fruit juices contain large numbers, >100, of yeast species derived from the orchard/vineyard.[23,27,58,144,153,179,194,215,283] Other yeasts contaminate juices from the juice-extracting equipment.[27] Most yeasts will not proliferate in juices and can be regarded as hygiene indicators. In addition, yeasts are generally heat sensitive and few will survive concentration of juice or pasteurization. Yeast ascospores can survive temperatures up to 10°C higher than vegetative cells.[69]

Sugar is handled in a number of forms; granulated bagged, granulated stored in silos, or dissolved in water to give 67° Brix syrup, this latter form is known as simple syrup. Granulated sugar has a very low moisture content and as such will not support growth of microorganisms. Microbiological growth in sugar syrup will be slow because of the high osmotic potential produced. Yeasts reported in sugars and syrups include *Candida apicola, C. lactis condensi, Citeromyces matritensis, Cryptococcus albidus, Pichia anomala, P. membranaefaciens, P. guillermondii, Saccharomyces cerevisiae, Schizo-*

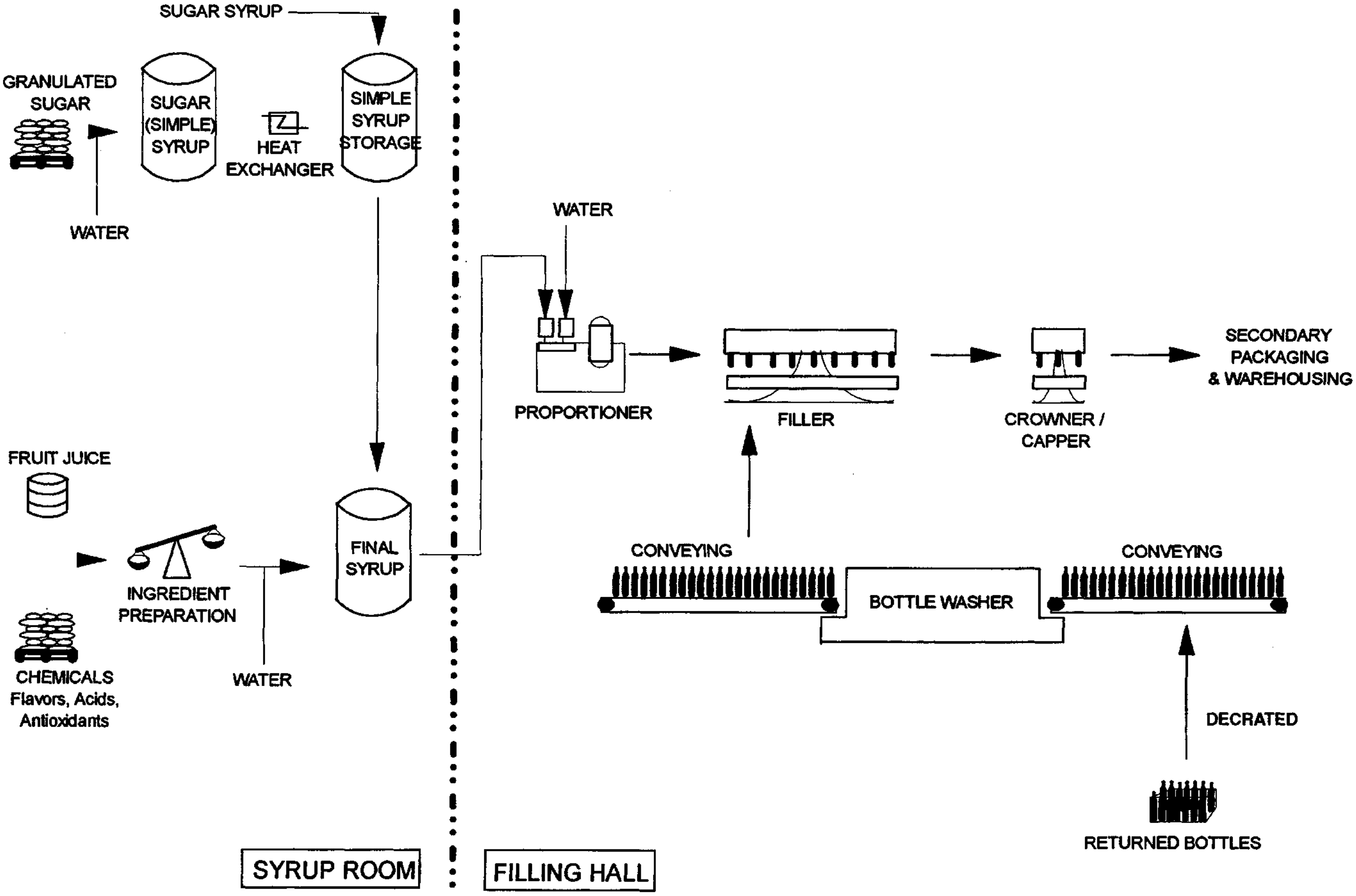

Figure 31-4 Schematic Diagram of a Soft Drinks Processing Plant.

---

saccharomyces pombe, Torulaspora delbrueckii, Zygosaccharomyces bailii, Z. rouxii, and *Z. florentinus.*[34,245–247,285,299] While contamination levels in sugars are typically fairly low, if there are deficiencies in storage conditions so that either granules become damp or syrups diluted, there will be an increased risk of microbial spoilage. Good Manufacturing Practice (GMP) should be employed to control these hazards, eg, storage of granulated sugar in dry areas. When handling concentrated syrup, formation of yeast and mold ascospores is a potential area for concern, particularly where products are later heat processed; typical heat treatments are insufficient to destroy ascospores.

Water is the principal ingredient in soft drinks and the quality of water should be closely monitored. Water may be treated by a number of processes, for example, ion exchange or reverse osmosis. Also included within the water treatment processes will be one, or a number of decontamination steps, typically using chlorine or UV light treatment. Water treatment steps must be carefully and routinely maintained in order to avoid high levels of microorganisms.[229] Sand and carbon filters should be backwashed and disinfected.

Additives such as acidulants, flavorings, colorings, antioxidants, or preservatives are also possible sources of contamination. Preservatives in particular are often assumed to be sterile but this is not so. Preservatives are usually added as sodium or potassium salts with little antimicrobial action until placed in a low pH beverage. Spilled preservatives can also allow adaptation to preservative by spoilage yeasts.

Packaging can be a source of microbial contamination where bottles are washed and reused, particularly in tropical environments.[45] Empty bottles coated with sugary residues are frequently permitted to incubate at ambient temperature for prolonged periods. Return of bottles to the factory represents a source of microbes, adapted to growth in preserved beverages. Ideally, returned bottles are kept segregated from production areas. Even after stringent bottle washing, problems can occur, notably mold pellicles remaining in bottles and mold ascospores in bottles, surviving pasteurization.

Aerial contamination in the environment of a soft drinks plant can affect contamination levels both in terms of geographic location[227,237] and local factors. Nearby sources of microbes, such as breweries, wineries, storage/processing of fruit or vegetables, or even sources of dust will obviously have an adverse effect. Such contamination is often highly seasonal, late summer presenting the greatest risk, because of fruit and vegetable harvesting, ambient warmth and dryness, all increasing the dust level that then enters via open windows and doors in the plant. Incidents are known where *Debaryomyces hansenii* and *Candida lambica (Pichia fermentans)* infections occurred in late summer, following demolition of nearby buildings and dust ingress through open windows. Aerial contamination obviously depends on the microbial loading and composition of the air. Mold spores usually predominate. About 95% of aerial flora over fruit orchards were found to be molds.[3] Many molds have evolved mechanisms for violent spore ejection into the air, ballistospores, or projection of ascospores by bursting asci.[128] Analysis of summer air showed the mold flora to contain very high proportions, 60% to 70%, of ascospores and ballistospores. Ingold[128] concludes "mold spores are essentially airborne" indicating that the aerial contamination route is likely to be most significant for molds.

Insects are probably the most important aerial vector for yeasts.[27] The relationship between yeasts and insects is only just becoming recognized,[145] despite the report a century ago that yeast will multiply in the crops of insects if fed on sugars.[109] Yeasts generally serve as food in one or more of the developmental stages of insects. Fruit flies (*Drosophila*) are often attracted to soft drinks, fruit juices, and fermented beverages. *Drosophila* in their natural environment consume many yeasts and exhibit a preference for certain species.[61] Studies of *Drosophila* spp. from oak-pine forests isolated 56 yeast species, many of which are significant to soft drinks spoilage (Exhibit 31-1). Yeast communities of insects were influenced significantly by insect habitat[146] but given the diversity of yeasts carried, insects such as *Drosophila* have potential to be very significant vectors of yeasts in soft drinks production.

Barnett, R.W. Payne, and D. Yarrow, *Yeasts: Characteristics and Identification,* 2nd ed., © 1990, Cambridge University Press.

Fruit Juice Manufacture

Fresh fruit can be regarded as routinely heavily contaminated with microorganisms, the majority being yeasts. Fruit juices from healthy fruit may contain 10^3–10^5 CFU ml^{-1}, whereas those from damaged fruit can be several orders of magnitude higher.[299] Small soft fruit with a large surface area, such as grapes, may yield as many as 10^7 yeasts g^{-1}.[269] An unpreserved fruit juice containing 10^3 fermentative yeasts ml^{-1} can be expected to spoil within 2 days at ambient temperature, although if refrigerated a shelf life of several weeks is possible.[268] However, most juices are given a heat treatment soon after extraction, either as pasteurization or in concentrate manufacture (Figure 31-3). During concentration, juices are subject to temperatures of 99°C for about 12 seconds,[46] a treatment sufficient to kill most vegetative microbes.[94] Fruit juice concentrates still contain some surviving microbes unable to grow at low pH and low water activity,[46] but are more likely to be recontaminated after cooling. While low a_w and pH in concentrates restricts spoilage to osmotolerant yeasts,[242,286,287] other yeasts may be found, often inhabiting a watery condensation slick, floating on top of the concentrate. Osmotolerant yeasts often grow slowly, particularly in sugar syrups but also in dilute media. Concentrates are an environment where osmotolerant yeasts can compete successfully against faster growing, osmotically sensitive yeasts.[66] Freezing or addition of preservatives to concentrates prevents microbial growth until reconstitution to single-strength juice. 70° Brix apple concentrate is stable for up to three years if chilled.[28]

Soft Drinks Manufacture

Soft drinks manufacture, including the bottling of fruit juices, is essentially a very rapid operation allowing little time for microbial growth in the bulk of the liquids. Final syrups for dispensing are prepared batchwise (Figure 31-4), sufficient for a few hours bottling. Production lines routinely handle 36,000 liters h^{-1} into glass or 30,000 liters h^{-1} into PET bottles.[45] Within soft drinks operations, microbial infection can occur through the raw materials, particularly juices, rarely through aerial vectors, or through microbial growth within the plant. Fruit juices are typically received in a concentrated, preserved format. While the microbiological quality of these juices is an important area to control, correct handling is also of key importance. Contamination and growth of preservative-resistant osmophiles, such as *Zygosaccharomyces rouxii* or *Z. bailii* in concentrates, can lead to contamination of the soft drinks operation by preadapted preservative-resistant spoilage yeasts. However, it has been estimated that 95% of yeast infections of soft drinks are caused by poor plant hygiene.[90] Sugary residues from soft drinks can build up on equipment used throughout the production process.[230,239,240,241] Yeasts and molds are capable of growth on these residues and can subsequently contaminate products. In order to avoid excessive contamination from equipment, all equipment should be hygienically designed without crevices or "dead spaces" to prevent accumulation and stagnation of product. Equipment should also be easily cleanable. Regular cleaning is essential to avoid build-up of microorganisms. Items of equipment most commonly associated with microbiological contamination and to which particular attention should be given are proportioners/proportioning pumps; carbonators; fillers, particularly filling heads; and sealing equipment/cappers (Figure 31-4). Yeasts found on equipment are often not spoilage organisms. Sand et al.[241] described *Candida sake* as the species most commonly found on proportioning pumps, yet to the authors knowledge never having caused spoilage. *Pichia anomala (Hansenula anomala)* is also commonly found and can cause spoilage.

Preservation procedures applied to soft drinks are not sufficient to guarantee complete sterility within packs, either by pasteurization or by using preservatives. Yeasts have been reported in 40% of commercial fruit juices[80] while Obeta and Ugquanyi[186] reported that up to 27% of mango and tomato juices contained heat-resistant molds. Contaminants are usually low in number and the great majority of such contaminants are not a cause for concern, being unable to grow or cause product spoilage. However, presence of fermentative spoilage yeasts, such as *Z. bailii*, at any level in a beverage is unacceptable. *Z. bailii* can grow and cause spoilage from one cell/package.[71,204] In an unpreserved beverage at ambient temperature, *Z. bailii* can cause spoilage within days, although it may take several weeks to develop sufficient pressure to rupture metal cans. Preservatives at normal concentrations will slow the growth of *Z. bailii* but spoilage will eventually occur, usually after between 4 and 8 weeks. The closed shelf life for pasteurized or preserved soft drinks is usually 6 to 12 months. It is often not appreciated that shelf life in this instance is not terminated by slow microbial spoilage but by organoleptic deterioration, often due to depletion of antioxidants and product oxidation.

A common sales outlet for soft drinks is through bars and restaurants; soft drinks are often prepared on-site via a "post-mix" concentrate and dispensing system. Post-mix systems frequently involve concentrated soft drink to which 4 to 5 parts water is added. Concentrates are supplied in stainless steel kegs or bag-in-box systems. These are linked via a dispensing system, where the product is proportioned with still or carbonated water. Microbiological spoilage has been reported in these post-mix systems. Problems have been attributed to incorrect handling of kegs; bad design of kegs, such that they cannot be correctly cleaned; nonadherence to daily hygiene routines around the dispensing head; and poor design of proportioning systems resulting in back flow of diluted syrup and subsequent spoilage. The organisms responsible for spoilage are similar to those commonly associated with soft drinks; however, there have been more frequent incidents involving Gram-negative bacteria, eg, *Gluconobacter*.[235] Spoilage is controlled with high levels of weak-acid preservatives and adherence to a regular cleaning and disinfection program. There is an increasing trend away from kegs toward bag-in-box because of the cleaning issue noted above.

31.4 MICROBIAL SPOILAGE OF FRUIT JUICES AND SOFT DRINKS

31.4.1 Characteristics of Microbial Spoilage

Soft drinks and fruit juices are acidic products, usually containing substantial amounts of fermentable sugars. Such an environment is ideal for spoilage by yeasts, molds, and for those few acid-tolerant bacteria. Spoilage in this context means microbial growth and metabolism, as opposed to incidental presence of nongrowing organisms. It is therefore not surprising that spoilage of soft drinks and fruit juices predominantly involves yeasts and molds. Out of 27 product recalls in 1993 in the US, 9 involved spoilage by yeasts and molds; other recalls were not due to microbial spoilage.[12] Microbial spoilage of soft drinks can cause clouds, sediments, and particulates. Fungal growth results in submerged mycelial masses or surface pellicles or destruction of cloud in citrus juices.[310] Taints may be produced, such as musty flavors formed from phenols by actively growing molds. Most spoilage yeasts are highly fermentative, forming ethanol and CO_2 from sugars. Ethanol imparts a characteristic sweet taste but excess pressure because of gas production is potentially much more serious. Yeast fermentations have been known to bulge cartons, split cans, and cause explosions in glass or plastic bottles or even aluminum kegs. An exploding bottle not only represents direct hazard but usually splashes the packaging of nearby containers. Mold growth on splashes may render large consignments unsalable.

The microbial ecology of most environments is likely to involve large numbers of growing organisms, smaller numbers of microbes unable to grow but held in stasis by factor(s) in the environment, and a few dying contaminants. Spoilage of soft drinks/fruit juices involves metabolism by growing microbes. Other microbes present as nongrowing contaminants represent a measure of hygiene in production.[69,71] Presence of such organisms should not be viewed with complacency because alterations in production can allow adventitious growth. For example, the presence of the ubiquitous yeast *Debaryomyces hansenii (Candida famata)* normally indicates poor hygiene, but can easily become a spoilage problem, given sufficient oxygen.

In a sweeping microbiological generalization, soft drinks and fruit juices are acidic broth media, usually high in sugars but low in assimilable nitrogen, phosphates, and oxygen. Low pH strongly suppresses bacteria and low temperature or high C/N ratio also favors fungi rather than bacteria.[283,287] Lack of oxygen, while restricting growth of many yeasts, almost entirely suppresses growth of filamentous molds. This results in a microbial flora dominated by fermentative yeasts, with molds and acid-tolerant bacteria where oxygen is sufficient.

31.4.2 Yeasts

Yeasts are fungi that exist predominantly as single cells. Some 600 species are currently recognized.[23] Many imperfect yeasts, classified as Deuteromycetes, are nearly identical to spore-forming perfect forms (Ascomycetes or Basidiomycetes), eg, *Candida famata* is the imperfect form of *Debaryomyces hansenii,* and similarly, *Brettanomyces* and *Dekkera.* Presence of either form indicates an environment suitable for both.

Major Spoilage Yeasts of Soft Drinks, Fruit Juices, and Concentrates

In 1985, Pitt and Hocking[204] assembled a list of 10 yeasts predominantly responsible for food spoilage, where foods had been processed according to normal standards of good manufacturing practice. Of these, seven are noted spoilers of soft drinks and fruit products: *Brettanomyces intermedius, Saccharomyces bailii, S. bisporus, S. cerevisiae, S. rouxii, Schizosaccharomyces pombe,* and *Torulopsis holmii.* The remainder can be regarded as opportunistic spoilers: *Candida krusei, Debaryomyces hansenii, Kloeckera apiculata,* and *Pichia membranaefaciens.* Of the yeasts reported in soft drinks, fruit juices, and concentrates, we have assembled a list of the 11 most significant spoilage organisms (Exhibit 31-2), in terms both of frequency of occurrence and significance of damage. In addition to those on the Pitt and Hocking list, we have included *Dekkera bruxellensis, Saccharomyces bayanus, Torulaspora delbrueckii,* and *Zygosaccharomyces microellipsodes. Dekkera naardenensis (Brettanomyces naardenensis)* and *Dekkera bruxellensis (Brettanomyces intermedius)* have been implicated in spoilage of many foods, including beer and soft drinks. Most *Brettanomyces* species have similar spoilage properties[204]: sediments, floating particles and, characteristically, acetic and sour-fruity off-flavors. These yeasts are predominantly spoilers of low-nutrient soft drinks, such as cola, tonic, soda water, or clear lemon.[90,257] Fermentation is slow and spoilage may not be apparent for weeks. *Dekkera naardenensis* is unable to ferment sucrose while *Dekkera bruxellensis* ferments glucose and sucrose. These yeasts are characteristically sensitive to preservatives. *Saccharomyces cerevisiae* is the yeast commonly associated with brewing and baking. This ubiquitous yeast is an entirely domesticated organism with no known natural habitat.[224] Its appearance as a spoilage organism of soft drinks often indicates yeasts escaped from wineries, breweries, or bakeries. Brewer's yeast is the main contaminant in installations producing both beer and fruit juices.[168] Absence of *S. cerevisiae* in soft drinks plants in Iraq may be significant[237] given the lack of alcoholic bev-

erage production in this area. There are many strains and variants of *S. cerevisiae*; 130 are listed by Barnett et al.[23] Strains show considerable variation in resistance to preservatives[302,304] from moderate to highly resistant. *S. cerevisiae* is a highly fermentative yeast, fermenting glucose, fructose, or sucrose with ease. Growth of this yeast is fast; optimal doubling time for diploid/polyploid strains is 2 hours while haploid strains can double in 75 minutes. Spoilage results in alcoholic fermentation, pressure build-up, and clouds and haze in the beverage.

Saccharomyces bayanus is currently recognized as a distinct species, but with considerable homology with *S. cerevisiae, S. paradoxus,* and *S. pastorianus.*[296,297] *S. bayanus,* previously known as *S. uvarum,* can be regarded as near-identical with *S. cerevisiae* in terms of spoilage of soft drinks.

Saccharomyces exiguus (Candida holmii, Torulopsis holmii) is encountered in spoilage in brines and shows vigorous fermentation of a limited range of sugars, including glucose and sucrose. It is moderately preservative resistant and growth is poor above 35°C. Appearance and spoilage characteristics are generally similar to *S. cerevisiae.*

Schizosaccharomyces pombe is a fission yeast, in appearance long cylinders with rounded ends, growing by dividing centrally. This is a highly fermentative yeast, fermenting both glucose and sucrose. It is osmotolerant, growing in 50% glucose, highly preservative resistant, and grows well at 37°C. Fortunately, this a relatively uncommon spoilage yeast, perhaps in consequence of its very slow growth rate, doubling time *ca.* 4 hours.

Torulaspora delbrueckii (Saccharomyces rosei) is a round budding yeast often found on fruit such as grapes. It is osmotolerant, growing in 60% glucose, and is noted for spoilage of unpreserved concentrates.[242] It is a fermentative yeast, fermenting glucose easily but sucrose poorly. *T. delbrueckii* is frequently found as a contaminant of soft drink plants but rarely caused soft drinks spoilage because of its sensitivity to preservatives, such as benzoic acid.

Zygosaccharomyces bailii is a yeast renowned both for its phenomenal resistance to preservatives and for the damage caused in spoilage of soft drinks, juices, concentrates, jams, wines, and ciders. Spoilage is characterized by sour taste, sediment, and slow fermentation up to very high pressures. *Z. bailii* grows relatively slowly, with a doubling time of *ca.* 2.5 hours. It has been described as a fructophile, fermenting fructose strongly in preference to glucose, and sucrose very poorly. This phenomenon is because of selection by the sugar transport permeases of *Z. bailii.*[86,266] The natural habitat of *Z. bailii* appears to be fruits, fermenting fruits, or mummified fruits[68,70] where its osmotolerance may be an advantage. It grows well in concentrates, at up to 50% glucose. *Z. bailii* has further advantages as a spoilage yeast in that it can grow from extremely low inocula, as few as 1 cell l^{-1}.[71,204] Cells can also become adapted to preservatives. Prior exposure to spilt preservatives in the factory can result in *Z. bailii* able to survive preservative concentrations 4 to 5 times the normally permitted levels. Interestingly, while *Z.*

bailii is a noted spoilage organism of wine, it can also make a positive contribution to flavors in wines during fermentation.[221]

Zygosaccharomyces bisporus is a yeast very closely related to *Z. bailii* and sharing its spoilage characteristics of slow fermentation, excess pressure, sediment, and haze. It is also a fructophile, and slightly more xerophilic than *Z. bailii*, growing at 60% glucose.[286] Variations between strains means considerable overlap, but generally *Z. bisporus* is less preservative resistant than *Z. bailii.*

Zygosaccharomyces microellipsodes has been described as "less dangerous than *Saccharomyces cerevisiae*"[236] in spoiling soft drinks but is capable of rapid spoilage of carbonated soft drinks, fermenting sucrose and glucose, and causing pressure increase and particulates. It is widely distributed in soft drinks plants and is moderately resistant to preservatives. It is unusual in its growth temperature maximum of just over 30°C.

Zygosaccharomyces rouxii is the most significant spoilage organism in concentrates, preserved or otherwise, in consequence of its extreme osmotolerance.[189] Its water activity limits are 0.62 a_w in fructose[250] and 0.65 a_w in glucose/glycerol.[286] It has been reported in a wide variety of foods and is also a significant cause of spoilage in soft drinks and fruit juices. Spoilage results from fermentation of sugars, particularly fructose. This yeast cannot ferment sucrose but, like *Z. bailii*, is reported capable of growth from very low contamination levels.[204] *Z. rouxii* also has a high degree of resistance to preservatives.

Recent research on spoilage yeasts involving physiology and RNA sequencing has uncovered a new species, *Zygosaccharomyces lentus*. This organism, isolated from spoiled orange juice and drinks, wine, and tomato ketchup, is fermentative, shows preservative resistance comparable with *Z. bailii* and tolerance to 60% sugar. Unusually, this yeast grows at 4°C and could pose problems in juices stored at chill temperature (H. Steels & S.A. James, pers. comm.—British Yeast Meeting, 1998).

The "Forensic Approach" to Soft Drinks Microbiology

Another approach to the microbiology of soft drinks is the "forensic approach" to contamination and spoilage.[71] This relies less on names of organisms and more on the ecological characteristics of groups of organisms. From this, likely significance of microbes in the factory can be determined and, in reverse, the microbes can be used to reveal the history of a beverage and likely sources of contamination. Contaminants are divided into four groups: Group 1—Spoilage; Group 2—Spoilage and Hygiene; Group 3—Hygiene; and Group 4—Aliens. Table 31-2 lists those yeasts reported in soft drinks and indicates their likely role in this context. Table 31-3 similarly lists yeasts reported in concentrates. Group 1 characteristics in soft drinks are fermentation of sugars, generating gas, and preservative resistance, examples being *Zygosaccharomyces bailii* and *Saccharomyces cerevisiae.* Group 2 includes *Debaryomyces hansenii,* whose presence normally indicates poor hygiene but can cause spoilage where conditions allow, eg, by oxygen ingress. Acetic acid bacteria are also included in this group of microbes. Group 3—Hygiene indicators, includes the ubiquitous yeast *Rhodotorula glutinis.* Group 4—Aliens includes microbes that are out of place in this environment. It is possible that some aliens reported in the literature may represent misidentification. Interestingly, recent taxonomic studies have shown a close relationship between Group 1 soft drinks spoilage yeasts.

The Zygosaccharomyces/Torulaspora *Superfamily*

Assessment of the dominant spoilage microorganisms of soft drinks, juices, and concentrates reveals a number of characteristics, common to all or present in many. These are: (1) fermentation of sugars, (2) fructophilly, preference for fructose, (3) preservative resistance, and (4) osmotolerance.

Recent taxonomic studies[132] based on 18s ribosomal sequences have revealed a close relationship between many of the dominant spoilage organisms of soft drinks (Figure 31-5). *Zygosaccharomyces bailii* and *Z. bisporus* are very closely related, and linked to *Z. rouxii* and *Z. mellis.* Also close are *Torulaspora delbrueckii* and *Z. microellipsodes.* This independent study confirms the physiological similarity of these spoilage yeasts and suggests that these are taxonomically genuine species.

31.4.3 Molds

The fungal kingdom in general is much better adapted than bacteria to life at low pH. Low pH is preferred by fungi; indeed for most fungi, a pH value near neutrality represents an upper limit to growth. Taxonomically, the fungi are grouped largely according to production of sexual spores. This is widely recognized as an artificial distinction; many deuteromycetes are near-identical to other fungi in all aspects other than sexual spores. As a result,

many fungi are described as having two forms, perfect and imperfect, and taxonomically belong to different genera, eg, *Byssoclamys* is the ascospore-producing perfect form of *Paecilomyces* (Table 31-4).

Given sufficient oxygen, many molds thrive in soft drinks and fruit juices, typically growing near the surface as mycelial mats, sometimes forming aerial mycelia and sporulating. Juices may be clarified by release of extracellular pectolytic enzymes.[310] Because fruit juices are usually pasteurized, surviving organisms are predominantly heat-resistant molds or heat-resistant ascospores that may be activated by heat[88]; yeasts are generally heat sensitive.[21,75] Heat-resistant molds causing spoilage of soft drinks and fruit products include *Aspergillus ochraceus, A. fischeri, A. tamarii,* and *A. flavus, Byssoclamys nivea, B. fulva, Paecilomyces variotii, Neosartorya fischeri, Eupenicillium brefeldianum, Phialophora mustea, Talaromyces flavus, T. trachyspermus,* and *Thermoascus aurantiacum.*[21,88,291] Spoilage is also commonly caused by *Penicillium notatum, P. roquefortii,* and *Cladosporium* spp., molds also noted for survival of ozonation, filteration, and UV treatment.[104] Heat-resistant molds and ascospores are sensitive to preservatives[183] but are best controlled by low oxygen, careful selection of raw materials, and good plant hygiene.

31.4.4 Bacteria

The majority of bacteria will not grow in acidic media. Many are rapidly killed in such an environment, but a few are able to thrive at low pH, namely acetic acid bacteria, *Acetobacter* and *Gluconobacter* spp., lactic acid bacteria, *Lactobacillus* and *Leuconostoc* spp., Lancefield Group N streptococci,

Clostridium butyricum and *C. pasteurianum*, *Alicyclobacillus* (ex-*Bacillus*) *acidoterrestris*, *B. coagulans*, *B. macerans*, and *B. polymyxa*.[46,47,177] Bacterial spores, such as those of *Clostridium botulinum* will not germinate at a pH less than 4.5; although slow growth of *C. botulinum* at pH 4.1 has been reported in laboratory media.[261] *C. pasteurianum* and *C. buytricum* can grow at pH 3.6 and have been reported to spoil fruit juices.[47] *Clostridium* spp. from animal slurry were the causative agent in explosions in pear juice, pH 4.72.[28] Spores of *Bacillus licheniformis* and *B. subtilis* have been shown to germinate in tomato juice at pH 4.4 and to grow, gradually raising the pH to 5.0.[220] Such spores easily survive pasteurization but growth is dependent on availability of oxygen.[219,220]

Bacterial spoilage at low pH is most frequently associated with Gram-negative *Gluconobacter* (*Acetomomas*). These also depend absolutely on the presence of free oxygen for growth and are restricted by gas-impermeable packaging and minimal headspace.[234] Still drinks in plastic beakers are particularly prone to *Acetomomas* spoilage.[229] *Acetomonas* can be detected in large quantities in processing plants[228] but should be contained by normal plant hygiene. It is resistant to normal concentrations of preservatives and dimethyldicarbonate (DMDC), but grows only slowly in fruit juices.[46]

Lactobacilli and *Leuconostoc* spp., the lactic acid bacteria, are known to cause spoilage in fruit juices causing loss of astringency, slime, or ropiness in texture, pressure, turbidity, or buttermilk off-flavors.[21,47,195,226,229,231] Spoilage by lactic acid bacteria can occur where selected and adapted strains are allowed to build up in the plant.[229] Such bacteria can grow in products at pH 2.8 but are relatively heat sensitive[21,231] and lose viability in chilled juices.[195] Fruit juices, particularly tomato, may also be spoiled by species of *Bacillus*, *B. coagulans*, *B. macerans*, and *B. polymyxa*. The characteristic "flat-sour" spoilage of tomato juice is caused by *B. coagulans*, a thermophilic bacterium growing from 30°C to 60°C.[96,263] More recently, another acidophilic, heat-resistant spore-forming organism, *Alicyclobacillus* (formerly *Bacillus*) *acidoterrestris*, has caused concern. This can survive pasteurization, grows well at low pH, and is capable of spoiling fruit juices, fruit juice blends, and lemonade, producing off-flavors and visible growth.[48,77,164,200,270,311]

31.5 PRESERVATION AND PRESERVATION PROCEDURES

The multiple factors involved in preventing microbial spoilage of soft drinks and fruit juices including intrinsic factors present as part of the beverage, and factors and procedures instigated deliberately for suppression of microorganisms, can be broadly divided into physical and chemical methods of preservation.

31.5.1 Preservation—Physical

pH

pH value is probably the single most important factor in preservation of soft drinks and fruit juices. pH impinges on many aspects of preservation, in addition to direct interactions of protons with microbes. The impact of acidulants in taste and antimicrobial action is pH affected. Low pH greatly increases the effect of pasteurization, synergistically increases the effects of weak-acid preservatives, and also acts as an additional hurdle to the growth of microbes.[150]

The pH of most soft drinks and fruit juices is below 4.0. The great majority of heterotrophic bacteria are unable to grow at such a low pH value[35] with certain notable exceptions.[237] This is in marked contrast to the fungal kingdom, which is well represented in those few organisms able to grow at pH 0.0.[252] The optimum pH growth range of most fungi lies between 3.0 and 6.5. Spoilage yeasts and molds in rich media can grow at very low pH values (Figure 31-6). The yeast *Saccharomyces cerevisiae* struggles at pH 2.2, whereas the mold *Byssoclamys fulva* grows at pH 1.6. Most spoilage yeasts and molds grow at pH values greater than 2.0. These values are of minimum pH for initiation of growth. Growing yeasts and molds acidify media (Figure 31-7)[149,258] and may be found growing at a pH lower than those shown here. Pitt and Hocking[201,204] quote a minimum pH for growing *Saccharomyces cerevisiae* of 1.5 and *Candida krusei* of pH 1.3. Surprisingly, the preservative-resistant yeast *Zygosaccharomyces bailii* is not exceptionally resistant to low pH.[204] Proton efflux from yeast cells may be a consequence of raising internal pH but also may serve as a mecha-

nism to suppress bacterial competition for the available nutrients.

The mechanism of inhibition of yeasts by low pH remains a matter for speculation.[223] Possible sites of action by pH are external and membrane proteins,[62] particularly transport permeases, membranes[31] and acidification of the cytoplasm following penetration of protons into cells. Cytoplasmic acidification may prevent growth by inhibition of pH-sensitive enzymes like phosphofructokinase,[143] by interference in the role of pH_i in cellular signal transduction,[281] or by exhausting cellular reserves of ATP in pumping protons from the cell.[121,251] Most organisms endeavor to keep the cytoplasmic pH close to neutral[222] at least during growth. Stationary phase yeasts are known to allow internal pH to fall to below pH 5.2[53,126,127] in acidic media. Higher internal pH is thought to enable enzymes to function at or near their pH optima and also provide the driving force for active transport.[36] Proton removal from the cytoplasm appears to be a key factor allowing growth at low pH, involving oxidative metabolism,[243] polyol metabolism,[134] and plasma-membrane proton pumps.[110,244,309]

To conclude, low pH is the predominating factor affecting microbial spoilage of soft drinks, largely eliminating bacteria as spoilage organisms. Suppression of fungi by low pH requires a pH lower than 1.5. This is not organoleptically acceptable and other factors must be used in combination with low pH to prevent microbial spoilage.

Water Activity

Water activity (a_w) is a measure of water availability based on the ratio of water vapor pressure of the sample to that of pure water, at the same tempera-

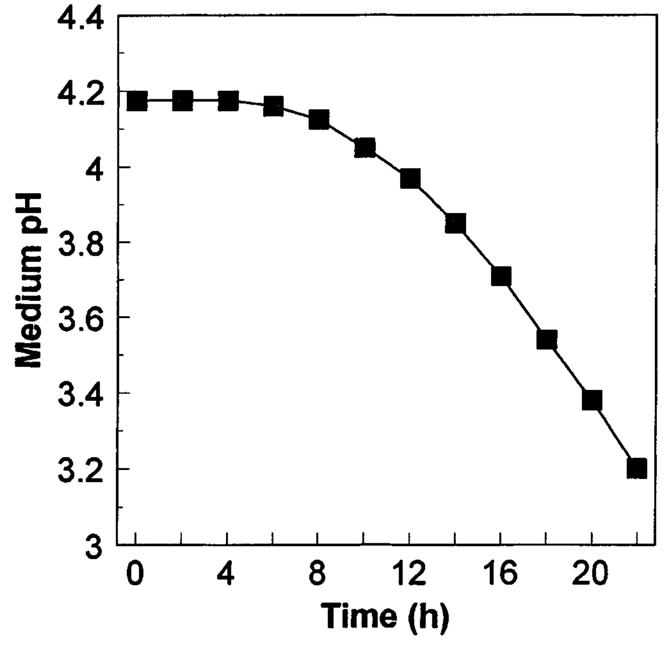

Figure 31-7 Reduction in Medium pH Caused by Yeast Inoculated into Sugar-Containing Media. *Saccharomyces cerevisiae* NCYC 1224 was inoculated, 1 mg dry wt. l^{-1}, into yeast nitrogen base media (Difco), containing 20 g l^{-1} glucose and incubated at 25°C.

ture. The principal solutes in soft drinks are sugars and organic acids. A 10° Brix soft drink has an a_w close to 0.993, and a 65° Brix sucrose concentrate has an a_w of 0.865.[51] Osmophilic or xerotolerant yeasts and molds[286] are defined as those able to grow at water activities less than 0.865[247] or 0.85.[201] Many molds can grow at an a_w of 0.80[51] including the spoilage molds *Aspergillus flavus*, 0.78, and *A. ochraceous*, 0.77.[204] Many yeasts can grow at a_w of 0.90. The average soft drink or fruit juice at 10° Brix has an a_w *ca.* 0.99 and offers little impediment to microbial spoilage.

Many spoilage yeasts of soft drinks are osmotolerant, notably *Zygosaccharomyces rouxii*, 0.62/0.65,[250,286] *Zygosaccharomyces bailii*, 0.80,[204] and *Debaryomyces hansenii*, 0.65/0.75,[65] which also can grow in the presence of 24% sodium chloride.[204] Osmotolerance undoubtedly enables growth of these organisms in fruit juice concentrates, which can act as inocula for spoilage of diluted products. We speculate that osmotolerance may aid infection of soft drinks via survival in concentrates, in mummified fruit, or in gummy droplets of dried soft drinks in unhygienic factories.

Pressure and Carbonation

It is generally recognized that modified atmospheres, particularly CO_2 enriched, can affect the growth of microorganisms (see Chapter 10).[82,136] Sparkling soft drinks contain carbon dioxide under sufficient pressure to have a major impact on microbial growth. Growth of some bacteria can be inhibited by as little as 5% CO_2,[54] and germination of some types of spores prevented.[87] Yeasts and molds are very resistant to such inhibition, 100% CO_2 at atmospheric pressure having little effect. Yeast in every brewery grows and ferments in a saturated CO_2 solution.

Pressurized CO_2 (carbonation) is generally known to be antimicrobial[173,254,260]; an effect that is often confused with a pressure effect or lack of oxygen. At 20°C, 3 volumes carbonation exerts a pressure of 2.6 bar (atmospheres), and 5 volumes, 4.8 bar.[172] Yeasts are inhibited by pressurized CO_2, not by pressurized nitrogen, showing that pressure *per se* has no effect.[154] Similarly, carbonation does not remove all oxygen from solution, indeed pressure will act to increase oxygen concentration. The degree of carbonation required to inhibit yeasts is of the order of 2 bar[2,91] although some 30 bar is required to kill them.[255] Inhibition was greatly increased by low temperature, an effect only partially explained by increased CO_2 solubility.[87] CO_2 in solution is in equilibrium with carbonic acid, bicarbonates, and carbonates and may be regarded as a weak acid with a pK_a of 6.35.[35] CO_2 can cross microbial membranes with great speed[283] and is known to have a central role in pH_i homeostasis. However, the physiology of growth inhibition argues against a role for CO_2 as a weak-acid preservative, although carbonation may exacerbate inhibition by weak acids.[152] Carbonation may interfere with amino acid uptake in yeast[142] but less so in bacteria.[82] Yeast cell division is prevented but cell volume continues to increase and DNA synthesis is unimpaired.[154] Work by Eyton-Jones[91] suggested inhibition of cell wall synthesis, possibly mediated via membrane-bound enzymes.

Pasteurization

Pasteurization is probably the most effective single method of preservation of soft drinks and beverages. The most probable target of heat damage is DNA, although membranes, RNA, ribosomes, and enzymes are also likely targets.[111] Pasteurization can be achieved "in pack" through use of a Tunnel pasteurizer, or by in-line pasteurization and hot-filling bottles, which are then inverted to heat the caps. Inline pasteurization and aseptic filling is a developing option. The advantages of pasteurization are low costs, reliability, and no carryover into the product. Disadvantages are capital investment, physical and organoleptic damage to the product, heat resistance of mold ascospores, and limited heat stability of plastic bottles.

Vegetative yeast and mold cells and asexual spores (conidia) are relatively heat sensitive. Two minutes at 52°C will kill most brewing yeasts,[155] while 10 minutes at 60°C kills almost all vegetative mold cells.[75,202,203] D_{55} for vegetative cells of *S. cerevisiae* is 0.90 minutes.[268] Effectiveness of pasteurization is altered by presence of sugars, salts, lipids, proteins, or preservatives[32,185]; sucrose in particular decreases its effectiveness,[63,64,108] and low pH increases the kill. Examples of pasteurization for orange juice range from 10 to 15 minutes at 70° to 75°C.[21] Carbonated products may also be pasteurized effectively, albeit at a slightly lower temperature.

Ascospores of molds present the greatest challenge to pasteurization of fruit juices. Ascospore-forming yeasts were shown to be marginally more heat resistant than non–spore-forming strains.[69,210] Mold ascospores, particularly those of *Byssoclamys fulva*, are considerably more heat resistant, with D values up to 12 minutes at 90°C.[25,33,141,203,209] Bacterial spores, such as those of *Bacillus licheniformis* and *B. subtilis*, can survive pasteurization in tomato juice. D_{90} values quoted are 29.9 minutes and 29.5 minutes, respectively.[219] Growth of *B. subtilis,* and to a lesser extent of *B. licheniformis,* is reported to be restricted by oxygen-impermeable packaging.[220]

Chilled Storage

Soft drinks and fruit juices may be preserved for a limited length of time by chilled storage. This is often used to extend the open shelf life of fruit juices, where it is recommended that after opening, products are chilled and consumed within 3 days (Figure 31-1). Most spoilage yeasts and molds are able to grow at 5°C, although slowly and temperatures close to zero are required to halt the growth of most spoilage yeasts. Bacteria such as *Lactobacillus plantarum* gradually lose viability in chilled juices.[195] Some fungal growth and spoilage is possible down to –7°C.[135,171,193] Molds, such as *Penicillium italicum,* can grow in chilled juices at 0°C; use of oxygen-impermeable packaging can double the shelf life of juices from 35 to 65 days.[310]

31.5.2 Preservation—Chemical

All microbes require certain key nutrients in order to survive or grow. In general, soft drinks contain fewer and more dilute nutrients than fruit juices, and consequently are much more microbiologically stable. A synthetic lemonade containing only citric acid, sugar, and carbonated water, for example, requires much less preservation than a fruit juice. Determination of limiting nutrients in soft drinks can be a difficult task, unless all other nutrients are present to great excess. Several nutrients can be at low levels, each becoming limiting if the concentration of others is raised, a situation identical to that recently highlighted in bacterial growth in drinking water.[169]

Sugars

With the exception of zero-calorie soft drinks, fruit juices and soft drinks contain excess sugars as carbon sources and are relatively low in other nutrients. The types of sugar present can have a profound effect on spoilage. Preservative-resistant yeasts, *Zygosaccharomyces bailii, Z. rouxii,* and *Z. bisporus,* utilize sucrose poorly if at all,[204] while the presence of fructose in a beverage positively encourages these organisms. Fructophily is closely associated with osmophilic spoilage yeasts,[287] an effect mediated by preferential uptake.[86,266]

Acidulants

Gardner[106] described the functions of acidulants as (1) flavoring agents, (2) buffers controlling pH, (3) preservatives, and (4) synergists to antioxidants. As antimicrobial agents, the effects of acidulants might be ranked in decreasing order of importance: (1) inhibition as a consequence of lower pH, (2) action as poor weak-acid preservatives, (3) inhibition by chelation of metal salts, and (4) modification of preservative action via buffering.

Inhibition of microbes by low pH (high proton concentration) is discussed in Section 31.5.1. Acidulants may act to exacerbate the effect of low pH by acting as proton carriers across the plasma membrane, in effect acting as weak-acid preservatives. Such a mechanism of action was suggested by observations that yeasts could tolerate lower pH if a strong acid like HCl was used as an acidulant, rather than phosphoric, citric, malic, tartaric, or particularly acetic acids.[201] These acids are known to have an antifungal effect at high concentration, 1% to 5%,[131,138,160,218] and also to inhibit bacteria at low pH.[137] Relative lack of preservative activity by di- and tri-basic acids, succinic and citric, may be because of the inability of these acids to diffuse through the plasma membrane lipids.[201] These acids have extremely low partition coefficients.[151] This is supported by reports of slow transport of citric and succinic acids into yeast.[275]

Many organic acids and acidulants bind metal ions with high affinity, varying widely with acid and ion[157,158]; highly charged ions of transition metals such as Fe^{3+} are bound most strongly. Stability constants for citric acid metal complexes are several orders of magnitude greater than those of other acidulants.[157,158] Inhibition of *Clostridium botulinum* by citric acid was found to be relieved by Ca^{2+}, Mg^{2+}, Fe^{2+}, or Mn^{2+} ions.[113] Therefore, it is probable that inhibition by citric acid is partly mediated by metal chelation, at least at higher pH where the chelating citrate ion predominates.

High concentration of acidulants in soft drinks has a considerable impact on buffering capacity (Figure 31-2). This may affect the impact of weak-acid preservatives on spoilage microbes. Weak-acid preservatives are more effective at low pH. Yeasts introduced into a glucose-containing medium immediately acidify the broth (Figure 31-7), enhancing the effect of weak-acid preservatives. Bacteria such as *B. subtilis* have been shown to raise the pH of tomato juice.[220] If acidulant buffers are present, the pH will be much less susceptible to change.

Microbial Nutrients: Minerals and Vitamins

Microbial stability of beverages is known to depend on the nutrient content, particularly nitrogen, phosphorus, sulfur, and vitamins.[217] Magnesium limitation slows growth of yeasts,[39] nitrogen or phosphate limitation causes cessation of growth and fermentation,[272,300] whereas lack of vitamins eg, inositol, can lead to cell death.[118,294] While the majority of molds are able to utilize nitrate as a nitrogen source, yeasts are generally more fastidious, requiring ammonium ions or amino acids. These are present in fruit juices, although nitrogen availability limits yeast growth in apple and grape fermentation.[125,174,272] Optimum level for growth varies between microbes, but generally concentrations of 1.75–5 mM NH_4 appear ample for bacteria, yeasts, and molds.[39] Pitt and Hocking[204] quote an example of an Australian product containing 25% fruit juice, withdrawn because of microbiological spoilage, and replaced with a stable beverage containing synthetic flavors and color. The critical nutrient in this instance is nitrogen.

Phosphates are also present in relatively low concentration in most soft drinks and fruit juices. However, phosphate requirements by microorganisms are much lower than those of nitrogen source—*ca.* 50 μM phosphate.[39] This can limit microbial growth in soft drinks.[300]

Micronutrients such as potassium, sodium, calcium, magnesium, manganese, copper, and zinc, while in low concentration in fruit juices, are in excess of requirements for microbial growth to 10^7–10^8 yeast cells ml^{-1}.[9,253] Micronutrients in grape musts are ample for yeast fermentation.[144] Recently, it was shown that removal of iron from grape juices using ion-exchange resins can render them less prone to spoilage.[95] Microbial vitamin requirements vary widely even at the species level, but are generally at the trace level. As little as 0.01 ng of vitamin B_{12} can cause a definite growth response.[9] Citrus and other fruit juices contain low concentrations of thiamin, riboflavin, and folates.[116,197] Addition of small quantities of vitamins to apple juices may promote yeast fermentation.[298] Thiamin deficiency can arise during storage of fruit juices, particularly when treated with sulfites.[256]

Oxygen

Of all the antimicrobial factors associated with soft drinks and fruit juices, oxygen availability is likely to have greatest impact on molds. There are very few anaerobic molds, exceptions being obligate anaerobes inhabiting intestines of ruminants[190] or low-oxygen stagnant water.[85] Of molds associated with spoilage, Miller and Golding[170] reported growth inhibition at 0.56 mg l^{-1} oxygen (1% v/v), Follstad[97] reported growth restriction at 0.5%, and spore germination inhibition at 0.1% oxygen.[276] Mold oxygen requirements are strain dependent but generally in excess of 0.05 mg l^{-1}. Fermentative yeasts, such as *Saccharomyces cerevisiae* or *Zygosaccharomyces bailii*, can be regarded as facultative anaerobes. Fermenting cells of *Saccharomyces cerevisiae* utilize oxygen for synthesis of unsaturated fatty acids and sterols, and trace amounts of these in media abolishes any oxygen requirement.[7,8] Lack of oxygen also restricts spoilage of soft drinks by many acid-tolerant bacteria. Spores of *Bacillus licheniformis* and *B. subtilis* are barely affected by pasteurization of fruit juices but, unexpectedly, require oxygen for spore germination and outgrowth in tomato juice at pH 4.4.[219,220] Gluconobacter are similarly oxygen dependent. Use of more gas-permeable plastic packaging may increase spoilage by these organisms.[220]

Natural Inhibitors

Many fruit juices and soft drinks contain natural inhibitors of microbial growth. These include essential oils or phenolic compounds,[74,196,284] polyphenols in apple juices, in particular chlorogenic acid,[148] limonene in citrus juices and peels,[178] herbal oils in colas,[24] phenolics in grapes,[22] or the antibacterial and antiviral components of tea.[181,289] Natural antimicrobial compounds appear not to be present in soft drinks in sufficient concentration to affect the growth of yeasts or molds. Possibly bacteria are more sensitive to these inhibitors. Phenolics in red grapes were reported to inhibit aciduric bacilli.[167,270] Similarly, use of thyme in alcoholic soft drinks[16] may inhibit bacteria through its carvacrol content.[59,60,140] Natural oleoresins have been used to inhibit growth of bacteria in alcoholic beverages for over 7,000 years.[163]

Weak-Acid Preservatives

Legally permitted preservatives of soft drinks and fruit juices are few in number. Those most commonly encountered are examples of weak-acid preservatives, sorbic acid, benzoic acid, and SO_2/sulfites. SO_2 has been documented as an antimicrobial in beverages for over three centuries.[225]

Weak-acid preservatives appear to share a common mode of action, despite their various chemical structures. All become increasingly potent as antimicrobial agents at acidic pH values, more being required in soft drinks at higher pH (Figure 31-8). In aqueous solution, weak acids exist in pH-dependent equilibria between uncharged acid molecules and charged anions. The proportion of undissociated acid increases as the pH declines. It is generally assumed

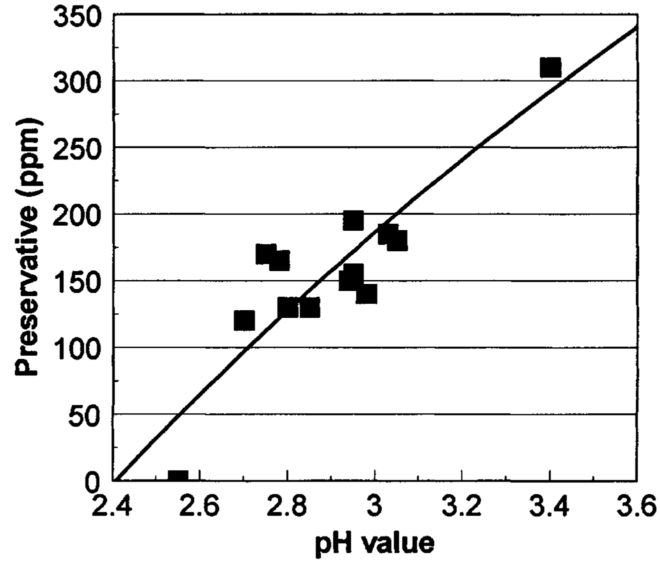

Figure 31-8 Scatter Plot of the pH of Soft Drinks against Preservative Content (Sorbic Acid + Benzoic Acid). Samples of preserved soft drinks were randomly selected from UK supermarkets in 1994.

that only undissociated acids have antimicrobial activity, although some activity by anions has been proposed.[83] The mechanism of action of weak-acid preservatives is thought to involve diffusion of lipophilic acid molecules through the plasma membrane into the cytoplasm[273,305] and dissociation into charged ions. Dissociation releases protons and the cytoplasm becomes increasingly acidic. Acidification of the cytoplasm may prevent growth by inhibition of glycolysis,[143] by prevention of active transport,[100] or by interference with signal transduction. pH_i is increasingly recognized as having a role in signaling.[281]

Resistance and adaptation to weak-acid preservatives has been reported in *Zygosaccharomyces bailii.*[302,303] Resistance may be due to a lower internal pH in resistant yeasts[35] as suggested in *Saccharomycodes ludwigii.*[274] Expression of a sorbate efflux pump has also been suggested[301,304,305] to account for development of resistance, but disputed.[56] The proton pumping H^+-ATPase has also been shown to be stimulated in *S. cerevisiae* in response to weak acids[89,121] although this mechanism appears unlikely in *Zygosaccharomyces bailii* given its poor growth at low pH.

Parabens; Esters of p-hydroxybenzoic Acid

Parabens is the collective term for the esters of para-hydroxybenzoic acid, which are permitted and occasionally used in soft drinks. These comprise the methyl, ethyl, and propyl esters, of which the longer propyl chain confers greatest antimicrobial activity[1] but lowest solubility.[50] In comparison to bacteria, fungi are much more susceptible to parabens.[72]

Parabens can be regarded as weak acids, the parahydroxyl group dissociating at high pH with a pK_a value of 8.5.[83] However, the mode of action of parabens appears distinct from that of weak-acid preservatives.[100] Inhibition is not pH dependent; parabens are efficient inhibitors at pH 7.0 and above (Figure 31-9A). No cross-adaptation to parabens was developed by yeasts grown in weak-acid preservatives[304] and parabens showed synergistic inhibition with several weak-acid preservatives.[216] It is possible that the main action of parabens is against cell membranes.[35] Reinterpreting the data of Oka,[187] Davidson[72] showed that inhibitory concentrations of parabens were directly proportional to that dissolved in the lipid phase. Parabens caused membranes to leak 260 nm–absorbing material[105] and are known to affect active transport in the plasma membrane.[81,100]

Dimethyldicarbonate (DMDC) and diethyldicarbonate (DEDC)

DEDC and DMDC (Velcorin™) can be used as effective sterilants for soft drinks, particularly when the microbial target comprises yeasts.[208] DEDC has been known as a fungicide for 40 years.[117] However, DEDC was banned in the US in 1972 because of erroneous fears of carcinogen formation[191] and DMDC has largely replaced DEDC.

Microbes are rapidly killed by addition of dicarbonates, faster kill being achieved by lower pH (Figure 31-9B), higher concentrations, and temperatures.[67,191,192] Dicarbonates break down rapidly in aqueous environments and thus pose no risk to the consumer, but offer no long-term preservative action. DEDC has been termed a "cold pasteurization"[50] acting only to sterilize but offering no extension of open shelf life.

31.5.3 The Inoculum Effect

The microbial load carried by a beverage will often determine whether a product will suffer spoilage. Large, healthy inocula will obviously shorten the time to spoilage and shelf life of the beverage.[38] The efficiency of many antimicrobial treatments is also dependent on inoculum. Heat treatments designed to cause a 5-log reduction in microbial count are ineffective if 10^8 cells ml^{-1} are present. Preservative efficacy by DMDC,[280] sulfites,[129,183] benzoic

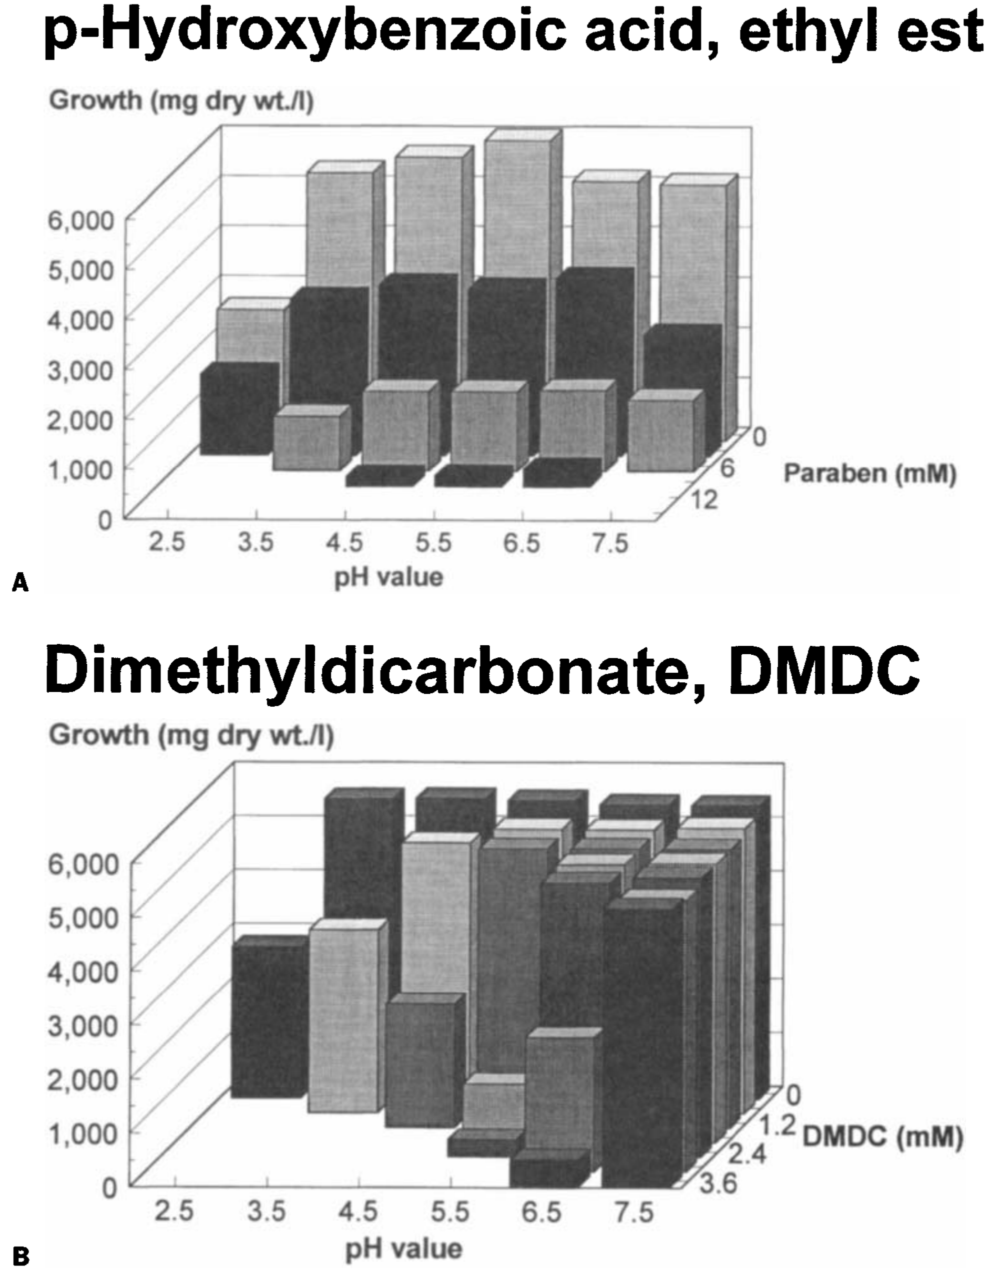

Figure 31-9 The Effect of pH on Inhibition of *Saccharomyces cerevisiae* X2180-1B. **A**, by Parabens, p-Hydroxybenzoic Acid, and Ethyl Ester. **B**, DMDC, Dimethyldicarbonate. Yeast, 1 mg dry wt l^{-1}, was inoculated into matrices of flasks, 50 mls YEPD, at the pH and preservative content indicated. Growth was measured after 3 days shaking at 30°C.

acid,[183,248] and sorbic acid (Figure 31-10) all vary with the inoculum level. More preservative is required to prevent growth from large inocula. Reduction in microbial load to 10 ml^{-1} or fewer will have a considerable impact on product stability. Possible explanations for inoculum effect include adsorption of preservatives by microbial cells, cell walls are known to adsorb organic acids,[147] stochastic increase in probability of inclusion of phenotypically resistant cells or mutants within inocula, or sufficient cell density to maintain cell to cell growth signaling. Recent work has proposed extracellular growth signals and in their absence, death of very dilute yeast populations.[211,213]

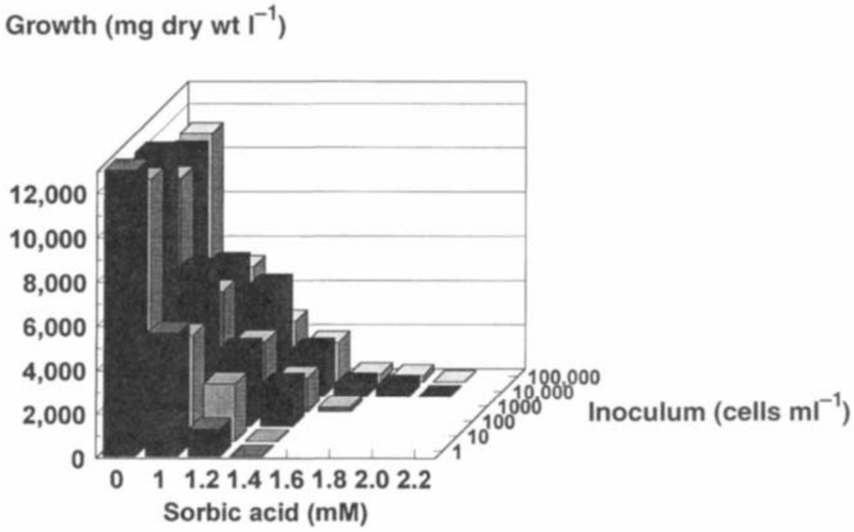

Figure 31-10 The Effect of Inoculum Size on Inhibition of *Saccharomyces cerevisiae* X2180-1B by Sorbic Acid. Yeast was inoculated into YEPD media, pH 4.0, containing sorbic acid at the concentrations indicated. Growth was measured after 9 days on an orbital shaker at 30°C.

31.6 MICROBIOLOGICAL SAFETY: RISKS TO HUMAN HEALTH

The risks to human health from microbial spoilage of soft drinks are relatively minor compared with other foods but nonetheless significant. Greatest risks are probably those associated with injury caused by exploding bottles. Ophthalmologists have noted exploding bottles as a serious cause of eye injury.[114] Spoilage of soft drinks is predominantly by fermentative yeasts, often capable of fermenting to high pressure, 6 bar.[204]

31.6.1 Pathogens

Human consumption of spoilage yeasts is generally unlikely to have adverse effects.[175] Of *ca.* 600 yeast species, very few are pathogenic to healthy humans.[23] However, recent developments in the medical field have resulted in a number of "new and emerging yeast pathogens."[115] Yeasts previously thought innocuous have been shown capable of damaging the human body, often by causing blood infections.[57,115,184] Several of these "new pathogens" can cause spoilage of fruit juices/soft drinks; notably *Candida famata (Debaryomyces hansenii), Candida guillermondii (Pichia guillermondii), Candida krusei (Issatchenkia orientalis), Candida parapsilosis,* and *Saccharomyces cerevisiae.* These new pathogens are almost exclusively of concern in immunocompromised patients and are very unlikely to affect healthy individuals, but add weight to the importance of preventing spoilage of soft drinks. Concern has also been expressed over minor intestinal disorders associated with consumption of *Saccharomyces* and *Zygosaccharomyces* yeasts.[180,290] These probably did not involve any infective process, and may be due to immunological responses to yeast antigens.[156]

Due to the acidity, pathogenic bacteria are rarely found or grow in fruit juices. This has led to the mistaken assumption that acidity causes rapid death of all bacterial pathogens, and stimulated a major food safety initiative by the President of the US.[55] The organism of concern is *Escherichia coli* O157:H7. This strain appears to have acquired a *Shigella*-like toxin gene and is capable of causing illness from a very low infective dose, *ca.* 12 cells.[44,262] Infection can cause death from hemorrhagic colitis and hemolytic uremic syndrome. It has been associated with animal feces from many sources, including cattle, and as a food pathogen in meat, animals, milk, and apple juice.[262] *E. coli* O157:H7 is acid tolerant, showing slight growth in apple juice in large inocula, 10^5 ml^{-1},[313] but from small inocula, 10^2 ml^{-1}, viability was maintained for 12 days and lost gradually over the next 3 weeks. Such behavior stimulated much research into bacterial acid habituation.[26] Several incidents were reported in the US concerning *E. coli* O157 in fresh pressed, unpasteurized apple juices.[42] Thirteen cases of infection were reported in Massachusetts in

1991, 10 in Connecticut in 1996, and 49 in California in 1996, including 1 death.[166] In all these cases, it is suspected that juices were expressed from apples contaminated with fecal material. Coliforms from animal manure have been shown to contaminate apples gathered from the ground in orchards and to persist through juice processing.[112] Resolution of this problem has centered around two approaches. One involves cleaning up in the orchard, removing animals, using fruit only from the tree and cleaning apples before pressing,[166] yet retaining the unpasteurized fresh apple taste in juices, the natural image, and a slight risk. The other approach involves pasteurization or use of preservative. *E. coli* O157 is heat sensitive, D_{52} is 18 minutes.[271] The bacterium loses viability within 2 days if benzoic acid 100 ppm is present.[313] Pasteurization in the presence of benzoic acid is particularly effective, D_{50} -0.64 minutes.[271] Note, in American parlance cider is unpasteurized apple juice, as opposed to the fermented beverage in the UK containing 4% to 9% alcohol.

Other examples of survival of pathogens in fruit juices include *E. coli* O134 contamination of orange juice by road dust[259] and *Salmonella typhimurium* contamination of apple juice, again from animal feces.[10] Research has shown that *Salmonella* spp. can survive and can grow in acidic media, down to pH 4.1[19,52,98,124,261] and raise the pH to tolerable levels.[137] Occurrences of salmonellosis in fruit juices are rare but finite.[10,112] *Salmonella* have been shown to remain viable in apple juice at pH 3.6 for 30 days.[112] The acid-tolerance response of *Salmonella typhimurium* has been shown to provide protection also against organic acids.[19]

Contamination of beverages by viruses, hepatitis A and small round structured viruses (SRSVs), has also been reported. One Australian incident involved 3,000 cases of infection by SRSV in orange juice. The source of contamination appears to have been contamination of potable water by waste water and sewage. *Cryptosporidium,* a parasitic protozoan found in animal feces, is a commonly reported enteric pathogen in humans. Infection usually occurs via contaminated water supplies but *Cryptosporidium* can survive in acidic conditions, pH 2.0 for 1 hour,[40] and has also been implicated in food poisoning following consumption of apple juice[101] and flavored fruit drinks.

31.6.2 Mycotoxins

Mycotoxins are a group of stable, toxic metabolites produced by molds, characteristically in late exponential or stationary phase (see Chapter 53). Mycotoxins are a widely recognized threat to human health[37,102] but expression of mold toxigenic potential is highly variable, even within the species or strain.[139] Given the range of toxigenic fungi in foods, Davis and Diener[73] suggested that "until proved otherwise, moldy foods and beverages should be considered dangerous and not consumed by man or animals." The toxin of particular note in this context is patulin,[13] found in apple juices as a result of mold growth on apples during storage. Patulin is regarded as both carcinogenic and mutagenic in addition to being acutely and chronically toxic,[73] although the degree of patulin toxicity has recently been questioned.[295] Patulin is produced by many species of *Penicillium,* primarily by *Penicillium expansum.* Patulin in apple juices may be eliminated by fermentation to cider or by ascorbic acid addition.[159] A rather arbitrary Maximum Permitted Concentration (MPC) of 50 μg l^{-1} is in force in some countries, such as Norway and Russia[306] and used in other countries as an advisory level.[13] In a survey of 113 Australian apple juices, 65% contained patulin, 29% at concentrations above 50 μg l^{-1}.[306] One roadside sample contained 45mg kg^{-1} patulin.[49]

Other mycotoxins produced by *Penicillium* spp., namely ochratoxin A, citrinin, and penicillic acid, have not been reported in fruit juices. Aflatoxin production is inhibited by caffeine[41,182] but this has been shown not to be true for ochratoxin A, found after mold growth on coffee beans.[15] Caffeine in tea-based soft drinks cannot be assumed to prevent mycotoxin formation. When considering the dangers of mycotoxins in foods, it is important to bear in mind that these are often stable molecules that persist in the food chain. Heat treatments kill molds but can leave high concentrations of mycotoxins to be carried through the manufacturing process into the final product.

31.7 CONCLUDING REMARKS AND FUTURE TRENDS

At present, microbial stability of soft drinks and fruit juices is largely determined by low pH, low oxygen content, pasteurization, and preservatives. Where it does occur, spoilage is predominantly by yeasts but new technologies may change this pattern of microbial spoilage.

31.7.1 New Processing Technologies

Throughout the food and drink industry there is an increasing trend toward natural, healthy products. One of the key criteria used to judge these parameters is the absence of artificial preservatives and additives, these also being controlled by increasingly tighter legislation. Another trend is the move toward plastic packaging. These two trends are providing an increasing number of challenges to the producers of soft drinks and fruit juices in order to consistently manufacture microbiologically stable, acceptable products. In order to address these issues, three main techniques are beginning to emerge. These are (1) hot filling, (2) aseptic filling, and (3) clean/hygienic filling. The first two routes are established technologies and their use is dependent on the willingness of the manufacturer to invest in the technology. However, neither of these methods is suitable for the production of carbonated soft drinks. Consequently, all the major manufacturers within the industry are currently investigating the use of clean, or hygienic, filling.

Hot Filling into Plastic Bottles

This technology is widely used within Japan, and an increasing number of hot-filled products are appearing throughout the world. For this technology, heat-set PET bottles are required, these bottles have a greater thermal stability than standard PET (85°C compared to the 50°C of standard bottles). Other new plastic packaging is being developed, resulting in plastic bottles that are stable to temperatures in excess of 100°C, these bottles include polyethylene-naphthalene (PEN) resin.

Aseptic Filling into Plastic Bottles

Aseptic filling is a technology now well established within the dairy industry. Increasing numbers of soft drinks manufacturers are moving toward aseptic filling into PET bottles. The filling equipment, high-hygiene environment, and associated control systems require a relatively high initial investment. The problems that still have to be overcome in aseptic filling concern the speed of lines, which is slow compared with traditional soft drinks filling operations (200 bottles per minute compared with 500). Furthermore, because of the design of aseptic fillers, it is not possible to fill carbonated products; hence, the development of clean-fill systems.

Clean/Hygienic Filling into Plastic Bottles

A number of different approaches are being taken toward clean/hygienic filling. As outlined in previous sections, the acidic environment of soft drinks limits possible spoilage microorganisms. Consequently, the degree of security designed into aseptic filling systems for low-acid foods is not required. Development of clean-fill systems is being approached from two directions. One route is to modify existing soft drinks production lines in order to reduce microbiological contamination, for example, by enclosing the filler in a clean room environment (class 100 filtered air) and chemically rinsing bottles prior to filling. The second approach is to take standard, slow aseptic filling systems and modify the filling, packaging, and disinfection systems in order to achieve the required increased line speed and ability to fill carbonated products.

Ultra High Pressure

Ultra high pressure (UHP) is currently used commercially within Japan for the production of jam and fruit juices. UHP treatments required are in the region of 4 Kbar. The use of high pressure is primarily seen as a milder option to the use of heat as regards damage to the product. To date, no systems are available for soft drinks, however, it is possible that in the near future, high pressure will be commercially attractive and used in order to vastly improve organoleptic quality.

31.7.2 Improvements in Hygiene: QA and HACCP

Spoilage of soft drinks and fruit juices is predominantly by yeasts. It has been estimated that some 95% of yeast spoilage can be directly attributed to bad factory hygiene.[90] Any improvements in factory hygiene are therefore likely to have a major impact on spoilage, particularly if targeted on likely sources of microbial contamination.

Traditional approaches of microbiological quality assurance (QA) of final products within the soft drinks/fruit juice industry rely on end-product analyses. Methods of sampling and inspection do not deliver reliable control as they are inaccurate, because of the nonuniform distribution of contaminants and results of analyses are retrospective. The ineffectiveness of this approach is illustrated by the number of product recalls as a result of microbiological contamination.[12]

Within the soft drinks industry, as with all other food industries, there is an increasing trend toward the use of quality management systems, such as Hazard Analysis Critical Control Point (HACCP). The HACCP system is a systematic approach to the identification and assessment of hazards and risks associated with the manufacture, distribution, and use of a particular food product,[161] in this case fruit juices and soft drinks. This is led both by increased legislation and recognition of the futility of existing end-product microbiological analysis. For example, recent EC legislation necessitates the identification of hazards using the principles of HACCP for all producers of food and drink.[11] It is hoped that identification of Critical Control Points within the soft drinks industy will lead to more attention to these areas and a consequent decrease in future incidents of spoilage.

32 Bottled Water

Donald W. Warburton and John W. Austin

CHAPTER CONTENTS

32.1 Introduction
32.2 Microbiology of the water sources
  32.2.1 Microbiological contamination of water sources
32.3 Microbiological contamination of bottled water
32.4 Production of bottled water
  32.4.1 Disinfection/sterilization of bottled water
32.5 The effect of storage on the microbiology of bottled water
  32.5.1 Indigenous bacteria
  32.5.2 Inoculation studies
  32.5.3 Biofilm formation
  32.5.4 Contamination of water coolers
32.6 Microbiological testing and criteria for bottled water
  32.6.1 Aerobic bacteria (ACC)
  32.6.2 Coliforms
  32.6.3 *Pseudomonas aeruginosa*
  32.6.4 *Escherichia coli*, fecal streptococci, sulfite-reducing anaerobes, and parasites
  32.6.5 *Aeromonas hydrophila*
32.7 Concluding remarks
References

32.1 INTRODUCTION

Bottled water, as defined by the United States (US) Food and Drug Administration (FDA), is "water that is intended for human consumption and that is sealed in bottles or other containers with no added ingredients except that it may optionally contain safe and suitable antimicrobial agents."[60] In fact, bottled water may include any potable water manufactured, distributed, or offered for sale in any sealed container, including bottles, carboys, cans, jugs, Tetrapaks™, and bags in a variety of sizes from <100 ml to 8 l or more. The source water for bottled water may be springs, wells, municipal systems, or other approved sources. Subsequently, the water may be distilled, carbonated, ozonated, and filtered depending on the quality of source water and the type of bottled water being manufactured; bottled water labeled as "natural" can only have a minimal treatment. Some bottled water may have added flavors, such as fruit juices and simulated flavors (see Exhibit 32-1 for definitions and approved sources and types of bottled water).

The bottled water industry in North America and the United Kingdom (UK) is currently experiencing an annual growth rate of 25%,[30,187] which parallels the growth of this industry worldwide. The dramatic increase in the consumption of bottled water has been prompted by consumers' concern over increasing water pollution, and by objections to offensive tastes or odors from municipal water supplies, and to fluoride, chlorine, and other additives. Increased consumer concern and awareness about health and fitness, changes in social attitudes toward alcohol, along with strong promotional advertising by the bottled water industry has also contributed to the dramatic and rapid growth of this industry over the last few years.[30,177]

The public has an unquestioning impression that bottled water is of good quality because it usually derives from a spring or underground source.[5,66,171] Bottled water is often promoted as pure, impeccably clean, and from scrupulously "protected" sources that are "unharmed by man." There is also the perception that natural-source waters have beneficial medicinal and therapeutic properties.[59,70] Because bottled water is manufactured, distributed, and sold, it is considered a "food" (as are other manufactured beverages) in many countries and is regulated by food standards.

Exhibit 32-1 Definitions of Approved Source Waters and Different Types of Bottled Water

Approved Source[95]	Approved source means the source of water whether it be from a spring, artesian well, drilled well, public or community water system, or any other source that has been inspected and the water analyzed, and found to be of a safe and sanitary quality (ie, is potable) with or without treatment.
Spring and Mineral Water[38,39]	
Spring water	Bottled potable water derived from an approved underground source (bore holes or springs that originate from a geological and physically protected underground water source and not from a public community water supply) that contains less than 500[a] mg l^{-1} total dissolved solids. Spring water may be treated to remove unwanted chemical and microbiological components but may not be labeled as "natural" (see below).
Natural spring water	Same as "spring water," and in Europe must meet the collection requirements of "natural mineral water" (as below) without any treatment to remove bacteriological components.
Mineral water	Bottled potable water obtained from an approved underground source (bore holes or springs that originate from a geological and physically protected underground water source and not from a public community water supply) that contains not less than 500[a] mg l^{-1} of total dissolved solids. In Europe, mineral water may be treated to remove unwanted chemical and microbiological components but may not be labeled as "natural" (see below).
Natural mineral water	**Natural mineral water** is mineral water (as defined above), but must meet the following conditions: it is collected under conditions that guarantee the original bacteriological purity; it is bottled close to the point of emergence of the source with particular hygienic precautions; it is not subjected to any treatments (other than removal of unstable constituents by decantation and/or filtration with the aid of aeration) that modify its essential mineral constituents; and cannot be shipped in bulk. **Naturally carbonated natural mineral water** is a natural mineral water that, after acceptable treatment, replacement of gas and packaging, has the same content of gas as the source. **Noncarbonated natural mineral water** is a natural mineral water that, after acceptable treatment and packaging, does not contain free carbon dioxide in excess of the amount necessary to keep the hydrogen carbonate salts present in the water dissolved. **Decarbonated natural mineral water** is a natural mineral water that, after acceptable treatment and packaging, does not have the same carbon dioxide content as at emergence. A **carbonated natural mineral water** is a natural mineral water that, after acceptable treatment and packaging, has been made effervescent by the addition of carbon dioxide from another origin.
Other Bottled Water[32,95,177]	
Artesian water	Bottled water from a well tapping a confined aquifer in which the water flows freely at the ground surface without pumping. It has been proposed that the collection of the water can be enhanced with the assistance of external pressure so long as such measures do not alter the physical properties, composition, and quality of the water.
Bottled water	Water that is placed in a sealed container or package and is offered for sale for human consumption or other consumer uses.
Carbonated or sparkling water	Bottled water containing carbon dioxide.
Distilled water	Bottled water produced by a process of distillation and has an electrical conductivity of not more than 10 µS cm^{-1} and total dissolved solids of less that 10 mg l^{-1}.

continues

Exhibit 32-1 Continued

Drinking water	Bottled water obtained from an approved source that has undergone special treatment or that has undergone minimum treatment consisting of filtration (activated carbon and (or) particulate) and ozonation or equivalent disinfection process.
Deionized water	Bottled water produced through a deionization process to reduce the total dissolved solids concentration to less than 10 mg l^{-1}.
Fluoridated water	Bottled water containing added fluoride in such an amount that the total concentration of added and naturally occurring fluoride does not exceed 1 mg l^{-1}.
Glacial water	Bottled water from a source that is direct from a glacier. Glacial water shall meet the requirements of natural water.
Natural water	Bottled water (such as spring, mineral, artesian, or well water) obtained from an approved source that is from an underground formation and not derived from a municipal or public water supply system. This water has undergone no treatment other than physical filtration, iron removal, and that has not had any significant change occur in the total concentration of the major ions in comparison with the concentrations occurring in the approved source water.
Purified water	Bottled water produced by distillation, deionization, reverse osmosis, or other suitable process that contains not more than 10 mg l^{-1} of total dissolved solids. Water that meets this definition and is vaporized, then condensed, may be labeled distilled water.
Well water	Bottled water from a hole bored, drilled, or otherwise constructed in the ground, which taps the water of an aquifer. Well water shall meet the requirements of natural water.

[a]The "cut-off" value is 250 mg l^{-1} in the US.[60]

Source: Data from References 32, 38, 39, 60, 95, 177

Like most foods, bottled waters are generally not sterile products. Bottled waters can contain naturally occurring bacteria as well as bacteria introduced during processing or use.

32.2 MICROBIOLOGY OF THE WATER SOURCES

The initial microbiological content of bottled water is dependent on the type of water, the initial source, its location relative to the surface and sources of contamination, the surrounding bedrock and soil constituents, its oxygen and mineral content, as well as the water flow.

Several research groups have shown that many aquifers, down to 4,000 m, contain a variety of microorganisms (Table 32-1), sometimes at concentrations as high as 10^5 to 10^7 cfu g^{-1} of sediment or ml of water.[15,16,68,108,188] Other studies report that the initial indigenous microbial level of spring or mineral water (both the source water and immediately after bottling) may be less than 10^2 cfu ml^{-1}.[18,131,159] No doubt, these variations in bacterial content are related to the type of rock strata, the age of the water, the initial source of water, temperature, oxygen, and nutrient content.[74] Some types of bottled water use potable municipal water as the source; therefore, the initial microbial levels are usually very low. Bacteria indigenous to municipal-treated and other source water may be innocuous or opportunistic (secondary) pathogens (Table 32-1).

32.2.1 Microbiological Contamination of Water Sources

The risk of contamination of bottled water by pathogenic bacteria and parasites is high because both can be found in the source water and can contaminate water during processing. In addition to indigenous bacteria from the natural water source (Exhibit 32-1), bottled water may contain bacteria that enter as contaminants, including a wide range of indigenous saprophytic species (Table 32-1), human pathogenic contaminants,[18] and parasites.[47,151] Fecal contamination presents the most common and widespread source of risk to public health associated

with all types of drinking water. Water (from springs, wells, municipal supplies, and other sources) has been associated with outbreaks or sporadic cases of foodborne illness resulting from enteric pathogens such as *Aeromonas, Campylobacter, Escherichia coli, Pseudomonas, Salmonella, Shigella, Vibrio, Yersinia*, parasites, viruses, and other bacteria (Table 32-1).[1,13,18,34,45,47,51,84,87,88,91,97,109,151,171,176,177,182,184] Bottled water has been reported to be the source of the causative agent in cholera,[21,22] and typhoid[27] outbreaks, as well as the diarrheal condition known as "Traveller's Disease."[61,141] Except for these isolated incidents, there have been no major outbreaks involving bottled water. The use of contaminated distilled water in humidifiers has been the cause of asthmatic or respiratory illness, known as "humidifier disease."[177]

During the cholera epidemic of April to November 1974 in Portugal,[21,22] bottled mineral water was identified as one vehicle of transmission of the causative agent *V. cholerae*. The source water from two springs was shown to be contaminated. Although the bottled water itself was not cultured for this bacterium, epidemiological evidence implicated noncarbonated bottled mineral water but not the carbonated version. It was speculated that the source water was contaminated either via a nearby river and/or via sewage from nearby villages; river water may have seeped into the limestone aquifer because the water table was significantly lowered by a lack of rain. Limestone aquifers are notorious for developing fissures and channels through which underground water can flow rapidly without being purified. It was suspected that the initial source of *V. cholerae* was raw or poorly cooked cockles, and the contamination continued through fecal contamination of river waters. The pH of the spring water and noncarbonated bottled water would allow the *V. cholerae* to survive, while in carbonated products this bacterium died within 24 hours. It is not known from the published reports[21,22] if the manufacturing plants tested the bottled waters for bacteria as part of their quality control and assurance. After this outbreak, Portuguese health officials insisted that a deep well be drilled at a higher altitude (away from the river) and that ultraviolet water purification equipment be installed.[22] The bottlers also demonstrated that the well water and finished products of bottled water were free of pathogenic bacteria and safe to drink.

In general, waterborne disease outbreaks are a result of either poor protection of the source water (ground water, well, etc) or inadequate treatment. Microbial contamination of ground water has been responsible for large outbreaks of waterborne diseases, particularly gastroenteritis.[43] Use of contaminated, untreated ground water caused 35% of waterborne disease outbreaks during a 35-year period (1946–1980) in the US[120]; hepatitis A virus, *Shigella, Yersinia,* and *Giardia* species were implicated as the most frequent pathogens. Many intermittent contamination problems are caused by the overflow or seepage of sewage, surface water runoff, and periodic flooding over the well field. New bacterial populations may also colonize an aquifer by filtration from above, as well as by lateral migration.[68] This migration can occur over considerable distances (2 to 3 km) in unconfined sandy aquifers[68] and may be substantial in other ground water, such as granular aquifers where bacteria can be transported several hundred metres or more[74,75]; bacteria and viruses persist longer in ground water than in surface water.[20] Bacteria may be retained by soil and prevented from reaching ground water whereas viruses can pass through the soil reaching the ground water.[20] Viruses have been isolated from ground water flowing beneath landfill and treatment sites for domestic and agriculture sewage.[104]

The appearance of coliform and pathogenic bacteria in water supply wells suggests that some contaminating (nonindigenous) bacteria may survive for considerable lengths of time in ground water.[74] Recent studies of genetically engineered bacteria in aquifers have shown that survival can last from 1 to several months (and up to 1 year), depending upon the bacteria, soil conditions (including chemical contaminants, nutrients and moisture), and competition with indigenous bacteria.[74] *Salmonella typhimurium, Escherichia coli, Streptococcus faecalis,* and poliovirus (type 1) survived longer than 15 days in ground water stored at 22°C[16] while total coliforms, fecal coliforms, and fecal streptococci were reported to survive longer than 70 days in contaminated wells.[19]

32.3 MICROBIOLOGICAL CONTAMINATION OF BOTTLED WATER

In addition to the water source, the most likely sources of contamination are equipment used to pump or transport the water from its source to the bottling location, equipment used in processing or bottling the water, and the bottles and caps used. In an unsanitary manufacturing plant, contaminated bottles and caps can contain up to 10^7 cfu cm^{-2}.[176] Colonization of equipment by bacteria, such as *Pseudomonas aeruginosa,* can occur (Section 32.5.3). Exposure of the water to air and contact with humans and other animals during bottling are additional modes of contamination.[59]

If bottled water, is not produced under Good Manufacturing Practice (GMP), using Hazard Analysis Critical Control Points (HACCP) to manage microbiological hazards, it could be the source of major food poisoning outbreaks. In general, information concerning foodborne illness associated with Canadian domestic and imported bottled water is nonexistent, except for the isolated major outbreaks, already mentioned. No doubt this reflects both the general high quality of most products, and possibly the failure of epidemiologists and physicians to inquire about consumption of bottled water when investigating illness. Another factor may be that many of the bacteria found in bottled water can cause cases of mild, uncomplicated gastroenteritis that are self-limiting. Illnesses such as these are not likely to be reported and even less likely to have the causative agent determined.

Bacteria found in the final product may have the potential for causing disease (Table 32-1).[145,172] Recently, Payment et al.[145] demonstrated a correlation between bacteria released from reverse-osmosis filtration units and gastrointestinal symptoms. Although this study used domestic point-of-use units, the bacteria released are common to all filtration units including those used in the manufacture of bottled water (Table 32-1); therefore the potential for disease exists. These organisms may be secondary or opportunistic pathogens, such as *Acinetobacter, Flavobacterium, Pseudomonas,* and other genera (Table 32-1),[73,94,143,146,176] especially if present in high numbers.[172] Whether individuals who consume contaminated water suffer adverse health effects depends upon the bacteria involved, the number of bacteria ingested, and the individual's general health and resistance to that particular organism.[63] Opportunistic pathogens may cause illness with insidious onset after long incubation periods in immunocompromised persons (see Section 32.4.1).

Bottled water needs to be of high microbiological quality, especially if intended for use by vulnerable populations (pregnant women, the infirm, the elderly, or the very young) for the following reasons. First, up to 50 ml of water, when taken between meals, can pass immediately through the stomach into the intestine. Pathogens in this water escape the bactericidal effect of gastric juices in the stomach, reaching the intestine in the same numbers as initially ingested and subsequently triggering disease.[134] Second, the minimum infective dose of pathogens may be quite low when ingested between meals with limited amounts of water. Third, consumption of bottled water by vulnerable populations, such as the elderly, AIDS patients, HIV-positive individuals, and other immunocompromised persons, will probably increase as these populations increase[5]; in compromised hosts, intragastric bactericidal mechanisms may be impaired to the extent that any microorganism ingested may reach the intestinal tract.[133] It is known that bottled water has been given to hospital patients when there was uncertainty about the purity of tap water.[33] Contaminated water supplies might be a more significant source of infection than foods, especially for infants.[169] In other situations, contaminated water supplies often cause intestinal problems that go unreported because the problems may be short-lived and probably not associated with the ingestion of water.[7] The modes of transmission of bacterial pathogens through water include direct exposure via ingestion or contact with the contaminated water, and indirect exposure through ingestion of foods or products prepared with contaminated water, subsequent contact with infected persons or animals, and exposure to aerosols.[185]

32.4 PRODUCTION OF BOTTLED WATER

Only approved source water (Exhibit 32-1) that has been inspected, analyzed, and found to be safe, sanitary, or potable (by either federal, provincial, regional, or other health authorities) should be used for bottling. This will ensure that the water entering the bottling plant has low bacterial counts and is free from pathogens.

However, during production and distribution of all types of bottled water, the cleanliness or bacterial content of the source water can change dramatically at each step of the manufacturing process and during storage in bottles in the processing plant and on the retailer's shelves.[168] These changes can be brought about by contamination and by growth of the previously stressed, dormant, or starved indigenous microorganisms[168] because of an altered environment (increased temperature, oxygen, and nutrient levels).

At the bottling plant, further microbiological contamination of the water may also occur from equipment used to pump or transport the water from its source to the bottling location, equipment used in the processing or bottling process (such as deionizing columns and filters), as well as from bottles, caps, and environmental sources.[18,59,175,176] A common water treatment system for bottled water (not including "natural" water) may include filtration, demineralization, and purification (Table 32-2, Figure 32-1). Microorganisms present in the source water are trapped in the ion exchange and filtration units, and may proliferate and contaminate the final product if these units are poorly maintained (Table 32-1).[85,145,166,172,174] The microbial quality of water produced by these devices is extremely variable, and is a function of: (1) the contamination and nutrient content of the source water, (2) the service life of the filter, (3) the water temperature, (4) the frequency of static water conditions,[63] and (5) maintenance of the filters. Water from reverse-osmosis filtration units can contain 10^4 to 10^7 cfu ml^{-1},[144] while activated carbon filtration units can release from 10^2 to 10^5 cfu ml^{-1}.[63]

Contamination can occur any time during processing due to failure of hygienic practices.[119] Thus, Hunter and Burge[93] found *Staphylococcus epidermidis* and *S. humanis* in 6 out of 52 bottles of water, and in other studies, bottled water was found to contain coliforms, *S. aureus,* and *Enterococcus.*[162,176] Most of these bacteria can be attributed to poor GMP in the processing plant and possible contamination via plant workers.

However, based upon available information, bottled water sold worldwide by members of the bottled water associations has generally been found to be of good microbiological quality and is not considered to pose any microbiological threat. Bottled water associations, such as the International Bottled Water Association (IBWA) and the Canadian Bottled

Table 32-2 A General Review of Bottled Water Treatment Systems Allowed in North America[a]

Step	*Process*	*Examples*	*Purpose*
1	Source water collection	Artesian well	N/A[b]
		Tap water	N/A
		Glacial melt	N/A
		Springs, etc.	N/A
2	Aeration	—	Removes volatile organics
3	Filtration	Activated carbon filter	Removes solids, odors, organics, and bacteria
		Sand filter	Removes coarse solids
		Manganese filter	Removes sulfur, iron, and solids
4	Demineralization or purification	Water softeners	Removes total dissolved solids, coarse solids, and minerals
		Deionizer	Removes dissolved minerals
		Distiller	Removes dissolved minerals
		Reverse-osmosis filtration	Removes 90% of the dissolved minerals and coarse solids
		Cation, anion, or mixed bed filters	Removes minerals
5	Mineral adjustment	Mineral mix added	Improves taste, mineral composition, chemical (eg, fluoride) composition
6	Disinfection	Ozonation (0.4–0.6 ppm)	Kills bacteria
		Ultraviolet irradiation[c]	Kills bacteria
		Filtration (1–5 μm)	Removes bacteria and parasites[d]
		Carbonation	Lowers pH and kills bacteria
7	Handling of final product	Container filling	N/A
		Capping	N/A
		Coding	N/A
		Distribution	N/A

Water Association (CBWA), issue sound guidance to members on Good Manufacturing Practices for the production of bottled water. All bottlers should be encouraged to join such associations.

Treatment of the source waters is dependent upon the quality of the source water and the type of bottled water being manufactured. Some researchers feel that a minimal treatment for source waters must include filtration for cyst removal, together with disinfection to eliminate pathogenic bacteria and viruses,[63] although this may not be necessary to treat water from protected and approved sources. A filtration system to entrap parasites appears to be the most logical means of removal, provided it is properly operated,[122] and if effective chemical pretreatment (including settling and precipitation of macro or micro particulates) is accomplished prior to filtration.[123] Incorporation of this filtration process must be carefully managed because improper filter backwashing and instability of the filter media can provide opportunities for elution of the cysts into the final product.[63] Subsequent disinfection must be sufficient to kill all cysts; in some cases, the contact time required may be several hours.[86]

32.4.1 Disinfection/Sterilization of Bottled Water

Systems used within the bottled water plant to reduce microbial contamination can include carbonation, ozonation, and ultra-filtration (using a one

micron "Absolute" filter), and other treatments (Table 32-2). The need for a water treatment, including a disinfection system, in a bottled water manufacturing plant is related to the type of bottled water and the intended use.

"Natural" bottled waters (Exhibit 32-1) come from an "approved" protected and sanitary underground source, where contamination from bacteria, parasites, and viruses has been proven to be negligible or nonexistent because of the nature of the surrounding rock formations. By standards and definitions (Exhibit 32-1),[38,39] these bottled waters must contain the indigenous innocuous microflora and therefore cannot be subjected to any process to remove them.[9,38,39,95] However, much controversy surrounds the question of the potential pathogenicity of indigenous microorganisms in mineral waters. Many of these microorganisms may not be pathogenic under normal conditions but have been responsible for infections in special circumstances, such as in hospitalized patients debilitated by illness or treatments that undermine the body's defenses. Some authors advise that such patients should avoid drinking natural mineral waters[168,177] while others recommend these products.[138]

Certain populations or YOPIs (ie, the young, old, pregnant, and immunocompromised) are particularly susceptible to infection by bacterial contaminants and parasites. For this reason, Health Canada recommends that only disinfected bottled water (such as carbonated, ozonated, and UV treated) should be used by these populations.[177]

Similarly, the National Association of People with AIDS (NAPWA) recommends that "safe drinking water sources" include the following: (1) "bottled water that is from a protected source" (75% of bottled water) or (2) "that has been subjected to one of the following: distillation, reverse osmosis, or one micron filtration."[138] Both statements are supported and recommended by the report on a recent workshop dealing with waterborne cryptosporidiosis.[11] Although when discussing protected sources, this report states that "water from underground sources is unlikely to contain oocytes, if it is protected from possible contamination that results from intermittent mixing with surface water, and it has been consistently free of coliform bacteria when tested."[11] The use of a one micron "Absolute" filter for the removal of protozoan cysts and the other purification steps is consistent with Health Canada's recommendation for disinfection of bottled waters targeted for susceptible consumers.

In contrast, the UK Expert Advisory Group on AIDS[12] recommends that AIDS patients with CD4 cell counts below 200 mm^{-3} be advised to boil water (from any source) before drinking it, as a measure to prevent waterborne cryptosporidiosis. Persons with asymptomatic HIV infection and/or CD4 cell counts above 200 mm^{-3} should be apprised of the risks of cryptosporidiosis so they can make an informed decision about boiling water. Physicians treating other immunosuppressed patients should consider the need to advise patients to boil water, depending on the severity of the immunodeficiency and the likelihood that cryptosporidiosis, if contracted, would be severe and persistent.

As a means of controlling the bacterial content (aerobic colony count, ACC) and the normal proliferation of indigenous and contaminating bacteria in bottled water (not "natural" products), water bottlers should be encouraged to add a final disinfection step, such as carbonation or ozonation, to their manufacturing process. Adequate disinfection can be the most cost-effective public health insurance available provided the treatment reduces all pathogenic bacteria by at least 4 logs[62]; assuming that the initial bacterial load is low.

The pH of the bottled water can affect the bacterial growth in these products and the pH may be significantly lowered by carbonation of the water, which is not unexpected due to the documented antimicrobial action of carbon dioxide.[92] In one study, noncarbonated mineral water had a pH of 6.2 to 6.5, while the pH of carbonated mineral water was 4.9 to 5.1[25]; enteropathogenic bacteria declined more rapidly in carbonated water because of the lower pH and bactericidal effect of the CO_2.[25] Carbonated products sampled in Canadian studies had 0% to 4% rejection rates as a result of ACC, compared with 61% for other types of nontreated bottled water.[176] Similarly, Ruskin et al.[156] found the lowest ACC to be in sparkling or carbonated products sampled in the US Virgin Islands. Hunter[92] reported that in several studies only 3% to 8% of carbonated waters studied had ACCs >100 cfu ml^{-1}. In contrast, more than 52% (and up to 72%) of the still waters tested had ACCs >1,000 cfu ml^{-1}.[92] There is no published literature on flavored bottled waters. However, most sold in Canada have been found to be high in carbonation and would have the bactericidal effects of low pH and high CO_2.

Ozonation has also been shown to reduce counts substantially, retard bacterial growth, disinfect, and even sterilize the product.[176] Ozonation of some finished products is allowed by the bottled water associations and need is dependent upon the quality of the source water and the type of bottled water it will be marketed as, ie, "natural" bottled water cannot be ozonated while other bottled waters can be (Exhibit 32-1; IBWA and CBWA, personal communication).

Refrigerated storage will minimize bacterial multiplication in bottled water, and the consumer should be advised to keep bottled water refrigerated after opening,[6,66,156,176] especially those products that may be consumed directly from the bottle and stored between use. This will help deter growth of contaminants that are introduced from air entering the bottle upon opening and those introduced from oral contact. Water dispensers (coolers) that utilize the larger bottles should be equipped with refrigeration units.

32.5 THE EFFECT OF STORAGE ON THE MICROBIOLOGY OF BOTTLED WATER

32.5.1 Indigenous Bacteria

Indigenous bacteria remain at low numbers while the water is in its natural environment but commence rapid growth after the water is bottled.[131,176] Prolonged storage of most waters at room and refrigeration temperatures allows multiplication of both indigenous and contaminating bacteria to numbers $>10^4$ or 10^5 cfu ml^{-1}.[18,50,58,66,131,159,176] Some bottled mineral waters do not support bacterial growth (Warburton, unpublished data), which may reflect their high mineral content and the high osmotic pressure this would exert. The reasons for this altered growth include increased oxygenation of the water during the bottling process, the increased surface area provided by the bottle, trace amounts of nutrients arising from the bottle,[159] and the increased temperature of the bottled water compared with the source water.

Secondary growth may occur as some species die, autolyze, and provide nutrients for the growth of other species, such as heterotrophic enteric pathogens.[133,159] Even small numbers of potentially harmful bacteria can survive for long periods in noncarbonated water, and multiply, feeding on the products of lysis, or on the metabolites of autotrophs. Survival curves with a saw-toothed appearance are often typical of bacterial growth in water,[71] and this appearance is probably indicative of a repeating cycle of bacterial multiplication, followed by die-off resulting from a shortage of nutrients, then cell lysis, subsequent release of nutrients, and another round of multiplication[133]; although in some cases, the overall bacterial population slowly decreases over time. Long-term changes in the major heterotrophic bacterial populations of bottled water occur, which may reflect changes in nutrient availability, a decrease in viability of some strains, competition, antagonism, synergism, or other factors not yet understood.[131,179,180] Bacterial multiplication is more rapid and reaches higher numbers in bottled water stored in plastic containers than in those stored in glass.[50] This is probably due to chemical components or substances migrating or leaching from the container walls into the water. Other influences may include oxygen and other gases diffusing through the plastic containers into the water.

During storage at ambient temperatures in plastic and glass containers, growth commences 1 to 2 days after bottling and may result in populations of 10^5 to 10^6 cfu ml^{-1}.[140,176] Counts may occasionally exceed 10^7 cfu ml^{-1}. These results are consistent with other studies, where bacterial populations in commercial samples (10^3 to 10^6 cfu ml^{-1}) were higher than those found in water collected from the spring (10^2 to 10^3 cfu ml^{-1}).[70]

In a 1987–1988 Canadian survey of bottled water,[176] sample units representing 82 lots of bottled water were obtained from 40 manufacturers in Halifax, Montreal, Toronto, Winnipeg, and Vancouver regions. Approximately half of the sample units (410 in total, usually 5 per lot) were analyzed within 1 day of bottling while the other half (395 sample units) were stored at room temperature and analyzed after 30 days. At day 0, 91% of the bottled water had ACCs $<10^4$ ml^{-1}, while only sample units of distilled and glacial waters had ACCs $>10^5$ ml^{-1}. All samples of drinking, deionized, unfiltered, mineral, and spring waters had an ACC <100 ml^{-1}. After 30 days of storage, only a few sample units of distilled water had very high ACCs ($>10^6$ ml^{-1}) while the number of sample units of distilled, demineralized, treated, and bottled waters with ACCs between 10^2 and 10^6 ml^{-1} had increased by 30%. Throughout this study, coliforms, *Aeromonas* spp., and *Pseudomonas* spp. were not detected.

A variety of surveys, including routine monitoring/sampling of spring, mineral, and other bottled waters,[176] show a wide range of bacterial counts (ACCs) in these products. Generally, spring and mineral waters had lower ACC levels than did other bottled water. Out of the varieties of bottled water tested, distilled water tended to have higher ACCs and also contained coliforms and *Pseudomonas aeruginosa*.[176] In contrast, glacial and deionized waters had lower ACCs than did some water classified as "bottled or purified" waters.

32.5.2 Inoculation Studies

Studies have been conducted to determine the effects of postprocessing contamination, poor GMP/HACCP, and storage on the survival of contaminating bacteria and subsequently the quality of bottled water (Table 32-3). When low levels of bacteria (≤ 100 cfu ml^{-1}) were inoculated into bottled mineral and spring water (simulating low contamination), their numbers increased to 10^3 to 10^6 within 1 week (Warburton[181] and unpublished data). *Aeromonas hydrophila, Citrobacter freundii, E. coli* O157, and *P. aeruginosa* reached levels $>10^3$ cfu ml^{-1} within 2 days while *Salmonella typhimurium, S. senftenberg,* and *Serratia marcescens* multiplied more slowly, taking 5 to 6 days to reach these levels. Thus, pathogens can proliferate to harmful levels in bottled water even when the initial contamination levels are low.

Other inoculation studies were done with high levels of bacteria to simulate gross contamination of the source waters and final products by sewage or surface waters as well as extremely poor GMP in the manufacturing plant.[179–181] The latter could occur, for example, during filtration and purification steps (Table 32-2) when resin filters and activated carbon filters become overloaded and release concentrated nutrients and bacteria into the final product.[179] A variety of bacteria, including *Aeromonas hydrophila* and other pathogens, can proliferate and survive in inoculated bottled water stored for more than several weeks (Table 32-3 and Figure 32-2). When initially present in high levels, *A. hydrophila* could survive up to 60 days or longer in water stored at 22°C. The presence of other bacteria, such as *E. coli, Lactobacillus, Flavobacterium,* and especially *P. aeruginosa*, may enhance the survival of *Aeromonas* in bottled water.[179]

Warburton et al.[180] also studied the survival of *P. aeruginosa* and *Salmonella* when coinoculated into distilled water and other bottled water (Table 32-3). After inoculation in distilled water, the nutrient levels were sufficient to allow some growth (approximately 1 log) and subsequent survival of both *P.*

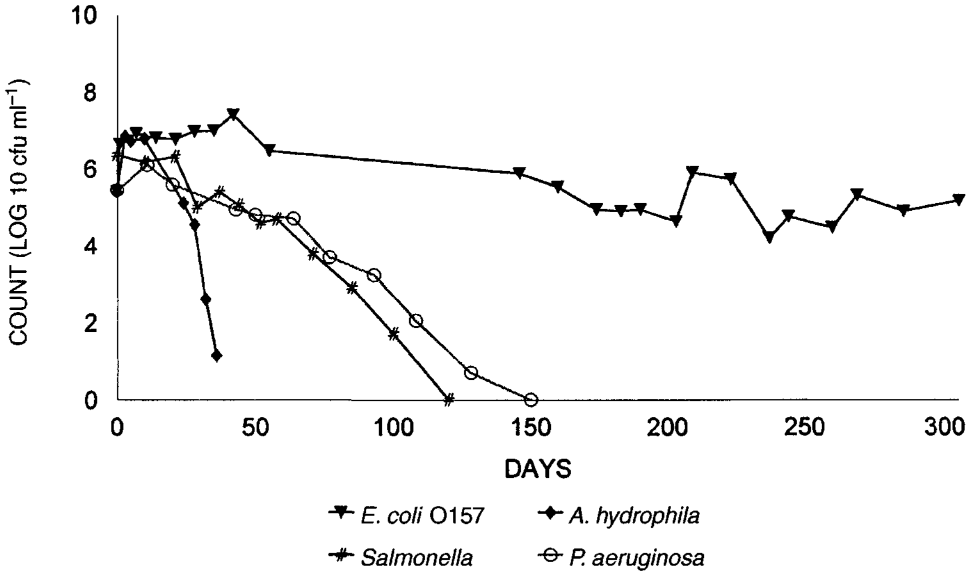
[b] Counts: log cfu ml^{-1}.

[c] NA: not applicable (sterilized sample); ND: not determined; PA: *P. aeruginosa* added; ACC-I: indigenous aerobic colony count; ACC-A: aerobic bacteria added; LAC/FLA: *Lactobacillus* and *Flavobacterium*; EC: *E. coli*; SS: *S. senftenberg*; SAL: *Salmonella* spp.

[d] UN: Warburton (unpublished data).

aeruginosa and *Salmonella* at high levels for up to 60 days; after this time, the bacteria quickly decreased in numbers, probably because of nutrient depletion. It is well known that enteric bacteria become stressed by nutrient limitations in aquatic systems, especially where organic material is persistently low.[130] The nutrients added along with the inoculum were likely to be insufficient to result in a pH change or allow the creation of toxic metabolites, so these are not likely reasons for the die-off. In these studies,[180] *P. aeruginosa* survived as the sole contaminant in distilled water for approximately 128 days. Alone, *Salmonella* survived in distilled water for 100 to 119 days. Together, both bacteria survived longer (>145 days). This seems to indicate that there is a synergistic effect between the two bacteria. Alone, *S. senftenberg* survived in distilled water for >158 days. Being often more resistant to heat and destruction by alcohol than other *Salmonella* serotypes,[178] it was speculated that this serotype may survive longer under these stressful conditions. It did so by at least 40 days.

Washing the cells before inoculation resulted in a less dramatic decrease in number compared with



These data parallel data for other types of bottled water (Table 32-3)

Figure 32-2 Survival of *Aeromonas hydrophila, Pseudomonas aeruginosa,* salmonellae, and *Escherichia coli* following inoculation into sterile distilled water stored at 22°C.[179-181]

unwashed cells,[180] and the former showed a prolonged survival time. Initially, after inoculation into the distilled water, the counts of both bacteria dropped 1 to 2 logs, but over several days the counts increased approximately 1 log, with both bacteria subsequently gradually decreasing in numbers. Then, in contrast to the *Salmonella*, the *P. aeruginosa* increased in numbers as the *Salmonella* continued to gradually die off. The increase in *P. aeruginosa* was probably due to a small but significant release of nutrients from the *Salmonella* cells. Subsequently, as the *P. aeruginosa* increased in numbers, the *Salmonella* began to increase, although with at least a 20-day lag. Washed cells of both bacteria survived >140 days.

The removal of nutrients from the washed cells may have resulted in a reduced metabolism and inhibited growth, and caused the cells to become dormant, thus prolonging their survival. Miniaturization of marine bacteria and decreased physiological activity are known responses to nutrient limitations that appear to extend their viability with time.[130] Many enteric bacteria are able to carry on a maintenance level of metabolism by hydrolyzing endogenous macromolecular reserves.[130] In contrast, the presence of nutrients, albeit low in concentration, possibly kept the unwashed cells in a state of active growth and more susceptible to die-off when nutrients became scarce.

The type of water (and thus the nutrient content) can influence the survival of bacteria (Table 32-3). *Pseudomonas aeruginosa* alone survived in distilled water for 128 days.[180] Alone, *Salmonella* survived in distilled water for 100 to 119 days, and in natural spring water for 116 to 162 days. When co-inoculated, both bacteria survived longer in the other varieties of water; the exception being the well water. Both *Salmonella* and *P. aeruginosa* survived longer than 135 days in spring, mineral, and tap water. Generally, these waters have a high mineral content (including trace nutrients) and could support bacterial growth for long periods of time as opposed to the inoculated distilled water. Other trials used the same combination of pooled cultures of both bacteria in five different bottled waters and these results show the effect of the water type on the survival of the bacteria. Again, the general trend is that when both bacteria are present, there is a synergistic effect, resulting in longer survival.

Previous studies[179] showed that *P. aeruginosa* enhanced the survival of *A. hydrophila*, which could survive up to 60 days or longer in water stored at 22°C, while *Salmonella* (in the presence of *A. hydrophila*) proliferated and survived up to 70 days. Burge and Hunter[25] also found that *S. typhimurium* was able to persist in bottled mineral water for at least 70 days.

Similarly, *Pseudomonas* spp. survived more than 140 days in mineral water bottled in both plastic and glass bottles.[190] *P. aeruginosa* survived in bottled mineral water for at least 70 days.[25] In contrast, Gonzalez et al.[70] found that *P. aeruginosa* survived and multiplied in mineral water, reaching values greater than 10^4 bacteria ml^{-1} and surviving longer than 1 year. At the conclusion of these studies, *P. aeruginosa* was called a "permanent contaminant" because of its ability to survive "ad infinitum."

The survival curves for *P. aeruginosa* published by Gonzalez et al.[71] are quite dramatic, showing large changes in growth and die-off, possibly because a single strain was used. Warburton et al.[180] used a pool of 10 *P. aeruginosa* strains and observed slight fluctuations between growth and die-off in the survival curves. Similarly, a greater fluctuation was seen when the survival curve of a single strain of *A. hydrophila* was plotted, as opposed to that of a pool of strains of this bacterium.[180]

In contrast, vegetative cells of *Clostridium perfringens* could not survive in a variety of types of bottled water even when inoculated at levels > log 3.0 (Table 32-3; Warburton, unpublished data). This bacterium did not multiply in any sample of bottled spring and mineral waters, decreased in counts by 3 to 4 logs within 1 week, and most strains completely died off within 2 weeks. One strain inoculated into mineral water and another strain inoculated into spring water (both stored at 21°C) survived longer than 2 weeks at counts < log 1.0 (after dropping > 3 logs within 1 week). Temperature abuse (storage at 37°C) did not affect the survival rate nor did it stimulate multiplication.

32.5.3 Biofilm Formation

In bottled water manufacturing plants, biofilms can play an important role in the survival of contaminating bacteria in pipes, filters, water reservoirs, and in the finished products. The proportion of bacteria adhering to surfaces is usually much greater than the planktonic population in the bulk fluid. Indeed, the majority of bacteria in aquatic systems grow within an expolysaccharide enclosed matrix.[41,121] Contamination of water from biofilms adherent to container walls may occur as cells are gradually released, or as large fragments of biofilm become detached from the walls.

Several authors have found higher counts and faster growth in bottled water stored in plastic or PVC bottles than in glass bottles,[18,50,140] however, this may be dependent upon the storage temperature.[70] At 22°C, bacterial growth was more rapid and reached higher numbers in mineral water stored in plastic bottles, while at 37°C growth was higher in glass bottles.[70] In contrast, De Felip et al.[48] demonstrated higher bacterial populations in mineral water stored at 20°C and 37°C in PVC, than in Tetrabrik containers and glass bottles (in that order). The inner surfaces of plastic bottles are rougher than that of glass, thereby promoting adhesion and colonization.[30] Also, residual cleaning agents in glass bottles (more so in recycled bottles) may inhibit bacterial growth.[18,30] The ability to adhere to plastic walls allows bacteria to utilize the few chemical components and organic sources that migrate to solid surfaces as well as the fatty acids, which may be liberated by lipase activity from the plasticizers.[50,73,159] Diffusion of gases through the walls of the plastic containers will aid bacterial growth in these bottles.

The colonization of surfaces enhances the capacity of bacteria to resist disinfection and starvation.[132] For example, *P. aeruginosa* had a lower mortality rate in water bottled in PVC than glass, which may reflect the capacity of this bacterium to colonize this type of material.[132] In contrast, the type of container did not influence the survival of enterobacteria.[132]

Long-term survival of bacteria in bottled water may be due in part to biofilm formation on the walls of the container.[173] Heterotrophs, *A. hydrophila,* and *E. coli* were able to survive in biofilms at levels of over 1,000 cfu cm^{-2} and higher for >21 days.[173] There was a fluctuation in the biofilm and planktonic counts,[173] which no doubt is a reflection of the continual incorporation of cells into the biofilm, sloughing off of cells into the liquid, as well as multiplication/die-off of the bacteria. Viable *E. coli* O157 was recovered more than 300 days after inoculation into sterile tap water.[181] Examination of the container by scanning electron microscopy demonstrated biofilms of *E. coli* O157, which had formed on the container walls. The cells were encased in exocellular material, probably exopolysaccharide. Large areas of the surface demonstrated empty cell wall sacculi, which remained after death and lysis of the biofilm cells. The contents released from the lysed cells may have provided nutrients for surviving cells to grow (cryptic or cadaveric growth) and form new biofilms.[133] Biofilms formed by *E. coli* O157 in nutrient-rich (tryptic soy broth) conditions[181] resulted in extensive adherence within 24 hours, with extracellular material quickly forming and increasing to levels that obscured individual cells. *Aeromonas, E. coli,* and other pathogens can become incorporated into biofilm communities, thus enhancing their viability.[173]

Some bottled water is low in available nutrients, and may be considered an oligotrophic environment. Bacterial biofilms on container walls probably form very slowly over a period of days or weeks. Warburton et al.[181] found sparse adherence and poor formation of biofilms by *E. coli* O157 in nutrient-limited (distilled water) after 10 days, although biofilms were present after 300 days.

32.5.4 Contamination of Water Coolers

In a 1992 study of water coolers in Quebec City, 28% to 36% of the water samples from these dispensers was found to be contaminated with coliforms, fecal coliforms, fecal streptococci, *Staphylococcus aureus,* or *Aeromonas* spp.[118] This contamination was not related to GMP of the production of the water in the bottled water plant but to the use of water coolers as the dispensers for the water.[118]

Whereas contamination of a water cooler by the bottled water supply can be controlled during production, the environment to which the water bottles and dispensers are exposed cannot be strictly controlled because there exists the possibility of contamination from the air and use.[54] The greatest potential for microbial contamination of bottled water occurs during bottle changing of water dispensers.[54] There is the possibility of contaminating the water in the dispenser with skin bacteria from the handling of the external bottle surfaces[54]; also, the reservoir is open to the air at this time. With some dispensers, the contamination route is the metal shaft used to puncture the caps to allow the water to drain into the closed reservoir.[54] If contaminants, such as *E. coli* or other bacteria, are on the bottle cap or the recessed plastic channel used to guide the neck of the bottle onto the metal puncturing shaft, then these bacteria will eventually be smeared across the shaft, or possibly migrate in any residual water, when pulling empty bottles out during bottle changes.[54]

Regular cleaning of water coolers and disinfection with hypochlorite should limit contamination.[118] In the 1992 study in Quebec City, only 44% of people possessing water coolers in residences and 36% of personnel possessing water coolers in workplaces had been informed of the necessity to clean and disinfect the equipment, let alone how to do it.[118] Because of this lack of information, a variety of products (including baking soda, vinegar, and dishwashing liquid) were used, rather than hypochlorite. Similarly, in a 1993–1994 survey of 48 Calgary schools using water coolers 80% to 90% never received any information on cleaning and maintenance procedures (K.G. Orom, Calgary Board of Education, personal communication). It is imperative that vendors and suppliers of water dispensers impress upon their clients the need for, and methods of, regular maintenance of their equipment[118] (K.G. Orom and personal communication).

32.6 MICROBIOLOGICAL TESTING AND CRITERIA FOR BOTTLED WATER

The examination of bottled water for indicators and some pathogens is essential after bottling.[116] Rather than examining water for the presence of all the possible pathogens using a variety of technically difficult, insensitive, time-consuming, and expensive tests, it is better to utilize relatively simple and more rapid procedures such as the detection and enumeration of indicator organisms.[168,171] Table 32-4 lists a variety of these indicator organisms that should be tested for, as suggested by the FAO/WHO Codex Alimentarius Commission,[37–40] the European Union,[9,10] Health Canada,[4] and the US FDA.[60] The presence of fecal indicators, such as coliforms, *E. coli*, streptococci, and clostridia (some of which may also be pathogenic) suggests that the water is potentially dangerous and was manufactured under poor GMP. One study found that the presence of indicator bacteria (at any level, even at very low levels of <10 cfu ml^{-1}) was associated with acute gastrointestinal disease.[192] The absence of fecal indicators is taken to denote the absence of bacterial pathogens, in general, and to indicate the product as being safe. The rationale for this is that pathogens are greatly outnumbered in feces by normal intestinal microorganisms.[168] The reliability of coliforms as fecal indicators is discussed in Section 32.6.2.

In Canada, bottled water is legally defined as a "food," although it has also been advertised for use in reconstituting baby and other foods, as nursery drinking water, for cleaning contact lenses, for skin care, and for filling humidifiers. Consequently, when offered for sale to the consumer, it must comply with all provisions of the Canadian Food and Drugs Act and Regulations.[4] Included in these provisions, for example, is Section 4 of the act that states that "no person shall sell an article of food that (i) has in or upon it any poisonous or harmful substance; (ii) is unfit for human consumption; (iii) consists in whole or in part of any filthy, putrid, disgusting, rotten, decomposed or diseased animal or vegetable substance; (iv) is adulterated; or (v) was manufactured, prepared, preserved, packaged, or stored under unsanitary conditions."

Despite the fact that bottled water is considered a food, some producers persist in recommending bottled water as suitable for cleaning contact lenses, reconstitution of rehydration mixtures, and the preparation of pharmaceutical agents. Water used in pharmaceutical preparations and drugs, and as a medical device, must meet the standards established by the regulatory agencies of each country for these products.

The standards for aerobic colony count (ACC), coliforms, and other bacteria are often expressed in terms of a 3-class attribute acceptance sampling plan, commonly referred to as a 3-class sampling plan.[89,90,96,175,176] The recommended parameters for bottled water are shown in Table 32-4, and the reasons for the standards are discussed in the following sections.

32.6.1 Aerobic Bacteria (ACC)

In surveillance programs conducted by Health Canada between 1981 and 1989, noncompliance of bottled water (noncarbonated and nonozonated) with the ACC standard[82,83] was generally quite high and ranged from 19% to >30%[175,176]; the incidence of noncompliance of bottled water with the coliform standard was lower (2% to 3%) but still significant.[176] These results parallel the noncompliance found in other Canadian studies[162,176] and in American studies.[7] All domestic carbonated mineral water samples were in compliance with the ACC standards. Since the ACC counts increase when the product is held at room temperature,[176] there is a subsequent increase over time in the number of lots out of compliance.

Despite the controversy over the effects of ACC on health (see Section 32.3), some authors[49,155,159] question applying an ACC standard to the final product for the following reasons.

1. Multiplication of bacteria in bottled water of low nutrient content is normal.
2. The ACC is not always an indicator of pollution.
3. The number of microorganisms per ml may not be an indicator of microbiological quality or healthfulness.
4. Indigenous bacteria may impute beneficial medicinal and therapeutic properties.

Bottled Drinking Water				
ACC at 22°C[g]	?	0	10^2 ml^{-1}	
ACC at 37°C[g]	?	0	20 ml^{-1}	
Total and fecal coliforms, fecal streptococci, *P. aeruginosa*[g] sulfite-reducing clostridia[g]	?	0	0 250 ml^{-1}	
D. United States (FDA)[42,60]				
Bottled Water				
coliforms by MPN	10	1	2.2 100 ml^{-1}	9.2 100 ml^{-1}
coliforms by membrane filter	10	1	1 100 ml^{-1}	4 100 ml^{-1}

[a] ACC standards should be applied to all bottled water within 24 hours of packaging. The number of sample units analyzed for coliforms is now 10, but will be changed to 5. *A. hydrophila* and *P. aeruginosa* regulations are in the process of being implemented through legislation.

[b] These guidelines are based on those of Codex[37] for the source water and critical control points.

[c] Bottled Drinking Waters (other than Natural Mineral Water) must meet public drinking water standards if obtained from a public water system or must be of safe and suitable quality (ie, potable) using multiple barrier treatments (filtration, disinfection, etc). Specifications for specific bacteria are under development.

[d] The number of sample units is not specified.

[e] Determined at 20–22°C in 72 hours on agar.

[f] Determined at 37°C in 24 hours on agar.

[g] Determined using ISO (International Standards Organization) methods.

Note: *n* = The number of sample units, usually selected at random, from a lot and examined in order to satisfy the requirements of a plan.

c = The maximum allowable number of marginally acceptable sample units per lot, ie, the number of sample units allowed with counts between *m* and *M*.

m = The maximum number of microorganisms per unit (ml) that is of no concern or is an acceptable level.

M = The number of bacteria per unit that indicate a potential health hazard, imminent spoilage, or gross insanitation, and if exceeded in any one sample unit causes rejection of the lot in question.

5. "Natural" bottled waters (Exhibit 32-1) are sold with the understanding and legal requirement that they have not been subjected to any treatment that would remove natural indigenous bacteria,[9,38,39] as these bacteria are believed to have therapeutic qualities.[59,70]
6. It has never been proven, despite the wide use of mineral waters, that indigenous microorganisms at the levels encountered have had any adverse effect on health.[49,159] Yet, susceptible populations are warned to avoid drinking natural mineral waters.[168]

However, ACC can be used as a means of verification of HACCP and GMP in bottled water plants. High ACC values may indicate poor GMP during the processing of the bottled water, especially when the ACC is determined within 24 hours of bottling, ie, before normal growth of indigenous bacteria occurs. A sudden increase in the ACC from ground water sources may be an early sign of pollution of the aquifer, and is useful in assessing the efficacy of the water treatment processes, such as filtration and disinfection, and as a measure of quality deterioration in distribution lines and reservoirs.[81] Thus, ACC can be used for quality control in the bottling plants. The ACC may be used to determine the suitability of the bottled water for use in the manufacture of other food and drink where, to minimize spoilage, the numbers must be low.[184,185]

Because ACC is more of an indication of GMP (rather than health and safety, which is determined by other indicators), Health Canada is recommending that the standards for ACC in bottled water be removed from regulations and that the ACC standard be incorporated by the bottled water industry into an industry-regulated code of practice, and that bottled water manufacturers be certified by government inspectors. Subsequently, when bottled water is tested for ACC within 24 hours of packaging and found to have excessive ACC, the cause or source of contamination should be investigated (by the quality control manager and health agencies), with identification of some of the contaminants to ensure public safety. Corrective action would then be taken by the manufacturer to improve the final product and when needed (ie, public safety is compromised) public recall or notification would occur.

High ACC numbers in bottled water may decrease the sensitivity of the coliform test,[66] and mask the presence of pathogens and opportunistic (secondary) bacteria.[125] They also increase the risk of exposure of susceptible populations, ie, the infirm, the elderly, and the young, to large numbers of opportunistic (secondary) pathogens.[65,66,145,157]

High ACC values may not indicate fecal pollution. However, when determined at higher temperatures such as 35°C on a rich medium, the ACC is more likely to recover fecal microorganisms that have contaminated the waters,[165,168] as such counts will be low or absent in waters of good microbiological quality.[115,116] Payment et al.[145] have shown that there is a strong correlation between water containing high ACC (obtained at 35°C) and gastrointestinal symptoms. ACC standards should be consistent and uniform for all types of bottled water (Table 32-4).

32.6.2 Coliforms

Coliform contamination may indicate a fluctuation of the source water quality, poor sanitation practices (or GMP) in the plant, and a loss of barrier protection of the sealed containers (ie, postprocessing contamination).[63,81] The absence of coliforms is generally believed to signify a safe drinking supply because pathogenic bacteria, such as *Vibrio cholerae, S. typhi,* and other *Salmonella*, die off at a much faster rate than coliforms.[129] However, waterborne illness epidemics have been reported in which pathogens have been isolated from waters that would have been considered safe by coliform standards.[52] The presence of opportunistic pathogens[94,146] in spring, mineral, and bottled water, as well as that of pathogens (including viruses) in general, is not adequately indicated by the coliform count.[52,65,101,103,131,184,185] For example, *Aeromonas* spp. have been detected when coliforms have not been.[129] The cysts of some parasites, such as *Giardia* and *Cryptosporidium*, are more resistant than coliform organisms to disinfection. Thus, the absence of coliforms in bottled water that has only been chemically disinfected will not necessarily indicate freedom from *Giardia* cysts, amoebae, and other parasites.[11,44,185] Therefore, the use of the coliform test by itself may not be adequate and, consequently, Canada is implementing the use of other indicators (*A. hydrophila, P. aeruginosa*, and others; Table 32-4) to ensure safety.

Thermotolerant (fecal) coliforms do not reliably predict the presence or absence of enteric viruses in a sample[52,55,126,127] as several enteric viruses are more resistant than *E. coli* to adverse environmental conditions.[57] Fifty-six percent of drinking water samples from various sources in Cairo, Egypt, were found to contain coliphage, while only 3% of the same samples were positive for total coliforms and fecal coliforms[55]; bacterial viruses (bacteriophages) are similar to human enteric viruses in terms of resistance to environmental factors.[76] Male-specific RNA coliphages have been proposed as indicators of fecal contamination of water.[78,79,183] These F-pilus specific bacteriophages (FRNA phages) require the presence of the F-pilus on the bacterial host for replication. Because the F-pilus is not produced at temperatures less than 30°C, FRNA phages cannot replicate in the environment. The inability of FRNA phages to replicate in the environment, combined with the high levels of FRNA phages present in human sewage, makes FRNA phages a useful indicator of fecal contamination. The use of bacteriophages as models of human enteric viruses in the environment has been the subject of a recent review.[77]

32.6.3 *Pseudomonas aeruginosa*

P. aeruginosa standards are included in Codex guidelines for source waters and natural mineral waters, as described in the "World-wide Codex Standard for Natural Mineral Waters,"[37,177] as well as in standards stipulated by the European Economic Community (EEC).[9,10] *P. aeruginosa* is cited as an indicator organism in the proposed new Canadian regulations for all bottled water[177] for the following reasons:

1. *P. aeruginosa* has been found in bottled water from a variety of countries, including Brazil, Canada, France, Germany, Spain, and the US.[70,84,136,155,177]
2. It does not occur in pristine springs.
3. The presence of *P. aeruginosa* can indicate serious contamination by pollution because it is associated with surface run-off,[168] human fecal matter,[84,160] and domestic and agriculture effluent.[186]
4. *P. aeruginosa* is an important indicator of water quality[52] because it has been the causative agent in waterborne and foodborne disease.[84,169,182] In hospital environments, especially for immunocompromised individuals, *P. aeruginosa* can cause diarrhea and can be life-threatening,[8] therefore special precautions would be justified.[169] For infants, contaminated water supplies may be a more significant source of infection by *P. aeruginosa* than foods[169]; it has been associated with illness in infants fed formula made with bottled water (reference 7 and Dr. F.A. Rosenberg, personal communication).
5. *P. aeruginosa* can also be used as an indicator of GMP because it can often be isolated from the final product, although it may not be detected from the source water. Contamination during bottling may be the result of colonization of equipment. Rubber seals or washers, linings, or coatings and grease containing organic compounds, even disinfecting soap, may all provide nutrients for this contaminant (Health Canada[168] and unpublished data).
6. Pathogenic isolates and other strains can grow in low nutrient water, such as deionized and distilled water[70,71,84,159,179,180] and can reach levels of 10^4 cfu ml^{-1} in mineral water,[71] thus increasing the risk of disease.
7. The presence of *P. aeruginosa* may impair standard coliform enumeration procedures.[3]
8. *P. aeruginosa* contamination can affect water color, clarity, and taste.[168]
9. Many of the *Pseudomonas* spp. isolates from mineral waters are highly resistant to commonly used antibiotics.[155]
10. *P. aeruginosa* potentiates the survival of *Aeromonas*,[179] *Salmonella*, and possibly other pathogens.

32.6.4 *Escherichia coli*, Fecal Streptococci, Sulfite-Reducing Anaerobes, and Parasites

Canada, Codex Alimentarius, and the EEC have specified limits for *E. coli*, fecal streptococci, sulfite-reducing anaerobes, and parasites in bottled water (Table 32-4). Similarly, Leclerc et al.[116] have indicated that bottled water analysis should include *E. coli*, fecal streptococci, and *P. aeruginosa*. As guidelines, the limits for these microorganisms can be used at the water source and at critical control points in the plant to determine the quality of the water and whether the plant is operating under GMP.

These microorganisms are useful indicators of fecal contamination.[29,110,168,186] Recovery of these organisms from any water source may mean that fecal material has gained access to the water, rendering it unfit for human consumption.[168] It is recommended that a variety of indicator organisms be included in routine testing to adequately ensure the safety of bottled water.

The detection of coliforms in the absence of *E. coli* can mean that a water source is contaminated with surface water or waters draining from surface soils. If fecal streptococci are recovered with coliforms, this suggests that the coliform contaminants have a fecal origin.[168] Thus, enterococci can be used to assess the significance of a doubtful coliform test, particularly if coliforms are found in the absence of fecal coliforms[184,185] or to confirm fecal contamination.

Zmirou et al.[192] claim that fecal streptococci are the best indicators of the risk of developing acute gastrointestinal disease when ingesting bacteriologically substandard drinking water. In general, fecal streptococci survive longer in well water than do coliforms and most enteric pathogens.[129] In a study of the occurrence of viruses in drinking water, enteric viruses or rotaviruses were detected in four samples that met acceptable levels of turbidity and residual chlorine.[105] None of the samples containing viruses had detectable total coliform bacteria; however, all samples containing viruses also contained fecal streptococci. Given their relatively high resistance to unfavorable external conditions, fecal streptococci are useful index organisms for viral contamination of water.[105,133] They are easily detected in water because of characteristics that readily separate them from other groups of bacteria.[56] Absence of fecal streptococci could indicate a safe water supply.

The spores of *Clostridium* spp. can survive longer in water than coliforms, *E. coli*, and other bacterial indicators, and may be used to indicate that contamination occurred some time ago.[168,184–186] Thus, one of the more attractive features of using clostridia as an indicator is that there is less concern about the time required to return the sample to the laboratory for assay.[26] Also, contamination of bottled water with clostridia could be indicative of ground water contamination or adulteration of the well or source with surface water,[160] or poor GMP.

Protozoan parasites such as *Giardia* and *Cryptosporidium* have caused recent waterborne disease outbreaks.[44,69,87,88,91,98,128] Such outbreaks, which include some due to municipal water, were the result of the contamination of surface water. However, 11% of the outbreaks between 1965–1984 in the US were caused by contaminated, untreated, and inadequately treated springs and wells.[44] A minimal treatment for source waters must include filtration for cyst removal, in series with disinfection for pathogenic bacteria and viruses.[63]

Although most manufacturers of bottled waters use "approved source" water that includes protected underground and further processed municipal supplies, some bottlers may use other sources. The source waters may include mountain streams, glacial waters, rivers, lakes, and ground waters, which have the potential for contamination with parasites. Several types of protozoa can be present in ground water and in very permeable aquifer layers[68] and bottled water in Mexico and France has been found to contain parasites.[47,151] *Cryptosporidium parvum* is transmitted by ingestion of oocysts spread by fecal contamination. *Cryptosporidium* oocysts are common in the environment and have been found in 65% to 97% of surface waters tested throughout the US.[114,153,154] A massive waterborne outbreak of watery diarrhea occurred in Milwaukee in 1993, which affected an estimated 403,000 individuals.[124] This outbreak was caused by *Cryptosporidium* oocysts that passed through the filtration system of a municipal water treatment plant. The likelihood of bottled water containing *Cryptosporidium* oocysts depends on the source.[11,124] In a study of an outbreak of cryptosporidiosis, Goldstein et al.[69] stated that "the use of bottled water was protective against this infection, but only if it were the sole source of drinking water." Bottled water derived from protected well or underground spring water sources is more likely to be free of *Cryptosporidium* oocysts than surface water. Water treatment before bottling, by reverse-osmosis filtration or distillation, will ensure removal of oocysts.[11] Water that has been passed through an "Absolute" 1 µm filter, but not a "Nominal" 1 µm filter, should not contain oocysts.[11]

32.6.5 *Aeromonas hydrophila*

Aeromonas hydrophila (Chapter 38) has been cited in the proposed new Canadian regulations as an indicator organism for the following reasons:

1. Bottled water from Canada, Saudi Arabia, Spain, and other countries[70,163,176] has been shown to contain *A. hydrophila*.
2. Although *Aeromonas* spp. have a poor correlation with survival of most other pathogens in water,[129] they can be discharged with, and isolated from, fecal matter,[167] may be considered as indicators of such pollution, and may have a correlation with fecal indicators in some waters.[14]
3. *A. hydrophila* has been implicated as a foodborne pathogen by an abundance of indirect evidence, is now considered by some workers a primary infectious agent,[167] and to cause waterborne disease.[26,109]
4. The presence of *A. hydrophila* (and other species) is indicative of inadequate good manufacturing practices. It seems prudent to recommend that individuals involved in the manufacturing, distribution, and preparation of foods, including water, consider *A. hydrophila* and other pathogenic *Aeromonas* spp. as undesirable in their products.
5. High levels of these bacteria may render these products unsafe. Pathogenic isolates of *A.*

hydrophila have been found to survive and proliferate to levels $>10^5$ cfu ml^{-1} in bottled water stored at room temperature.[179]

6. *A. hydrophila* has long been recognized as an opportunistic pathogen in hosts with impaired immune function.[167] Active steps may be needed to limit exposure of these populations to these potential enteric pathogens.[23]

32.7 CONCLUDING REMARKS

As with a great number of other foods, better education and communication between the bottled water associations, governments, health agencies, the media, the public (including susceptible populations), and retail outlets is badly needed. This should include the following:

1. **The types of bottled water and bacterial content.** Information on the differentiation between "natural" waters and other bottled waters is greatly needed. This information should include statements indicating that bottled water (especially "natural" waters) is not a sterile product and contains a variety of innocuous bacteria. Explanations about production under GMP, including statements about testing for pathogens and indicator bacteria would also be helpful.
2. **The handling of products.** Most persons assume that bottled water is sterile and fail to comprehend that bottled water can support a bacterial population. Having a natural bacterial content and being able to support contaminants should affect the manner in which the consumer (and especially susceptible persons) handle the product upon purchase. This should include refrigeration, proper preparation of infant formulas and other foods, as well as regular cleaning of water coolers and dispensers. Retail outlets must be encouraged to rotate their bottled water stocks on a regular basis so the consumer is purchasing the freshest product possible.
3. **Letters and communiques.** Bottled water associations, government, and health agencies should have information letters or communiques available on bottled waters to parallel those available for the safe use and handling of other foods.
4. **Labeling.** Labeling of finished products with the bottled water associations' logos or with a statement referring to membership in these trade associations would enable the consumer to purchase products produced under their strict and sanitary codes of practices.

Implementation of new standards and guidelines, as suggested in Table 32-4, is necessary to aid government agencies, food testing laboratories, and bottled water manufacturers in providing the public with the best product possible. It is not surprising that both bottled water and municipal waters contain the same microorganisms (Table 32-1) because both can originate from the same sources. These bacterial genera are found in products from a variety of countries, and many are a cause for concern because of their potential pathogenicity. When one considers that the target consumer populations may include pregnant women, the infirm, the immunocompromised, the elderly, and other susceptible people, bottled water must be shown to be safe. However, bottled water of excellent quality can be produced by following GMP/HACCP programs and by testing the source waters, in-line samples, and finished products for a variety of indicator organisms (Table 32-4) while using ACC as an indicator of GMP within 24 hours of production. New standards should include mandatory sterilization or disinfection of final products when bottled water is not manufactured from "approved sources." This would also include a mandatory filtration step or system to entrap parasites and their cysts. The definition of approved source needs to be well defined and even stated in regulations. Bacteriological analysis of approved sources must include all the indicator microorganisms listed in Table 32-4.

More extensive surveillance of the bottled water industry is recommended, especially of those manufacturers who are not members of the bottled water associations (eg, IBWA and CBWA). Public health officials should be encouraged to inquire about ingestion of bottled water when investigating waterborne and foodborne illness. More surveillance by government laboratories is often impractical because of limited resources. However, Geldreich[6] recommended a two-tiered monitoring approach whereby industry would conduct 90% of the monitoring, using certified labs, while government agencies would conduct the remaining 10% to verify data. This self-governing approach is consistent with both the aims of the IBWA and CBWA, which serve as self-monitoring trade associations.[187] The standards established by these organizations for the production of bottled water require that all plants be inspected on an annual basis by an independent agency in addition to government inspections. These organizations welcome additional and more stringent regulations.[187] However, not all bottled water manufacturers belong to these organizations and thus do not comply with their codes of practice.[95]

Each container should be marked with the bottling date, date of expiration, and lot number to assist the retailer and consumer in determining freshness.[66,156] These will aid in the follow-up of consumer complaints and the removal of product from retail shelves. Each container should be supplied with a protective seal to reduce the chance of contamination[6] and tampering.
